CHEMICAL AND MOLECULAR PROCESSES IN CONTRACTILE ACTIVITY

W. F. H. M. MOMMAERTS, Ph.D.
Cleveland, Ohio

ANY MODERN DISCUSSION on the chemical and molecular nature of cardiac activity is largely based on the presumed analogy between the processes in the heart and those in striated muscle. This is due to the circumstance that, while skeletal muscle has been the classical material for those biochemical researches which lead to present-day knowledge concerning myosin, actin, phosphocreatine and adenosine triphosphate (ATP), similar experimental investigations on cardiac muscle have been carried out only sporadically. While an upsurge of interest in this direction has become noticeable, we still have to lean heavily on information derived from skeletal muscle.

The chemical physiology of the heart seems to stand by itself only in one respect, namely, with regard to those processes which cause its automaticity. Morphologically, this regulation is ascribed to the nodal and conductive tissues. There has recently been an increased interest in the biochemical investigation of these tissues, as evidenced by valuable reports on its ionic composition (Davies, *et al*) and its lipid content (Robb and Mallov). In view of the resemblance between its task and that of nervous tissue, and of the importance of the acetylcholine system in the generation and conduction of impulses in the nervous system, we have recently investigated the distribution of cholinesterases in the heart. It appears that the myocardium contains an unspecific cholinesterase, while the Purkinje tissue is endowed with the specific acetylcholinsterase commonly found in nerve. This enzyme is characterized by a high rate of splitting of acetylcholine and, to a lesser extent, of β-methylacetylcholine; by a characteristic dependence of its activity upon the substrate concentration; and by its inability to hydrolyze butyrylcholine and benzoylcholine. The enzyme was found in the bundle of His and the AV-node in about the same amount as in typical peripheral nerve, and occurs also, in about half the concentration due to the admixture of connective tissue, in the moderator bands.

Returning now to the chemistry of the myocardium, the first question to be discussed is its dependence upon continuous aeration. Incorrectly, this is sometimes regarded as a sharp difference between cardiac and voluntary muscle. The purpose of metabolism—whether respiratory or glycolytic—is to generate high-energy phosphate compounds, primarily ATP. Much more ATP is generated by aerobic than by anaerobic dissimilation of foods. There are types of muscle which are well provided with all the enzymes involved in tissue respiration and aerobic phosphorylation, such as cytochrome oxidase, cytochromes, flavin enzymes, et cetera; sufficient to resynthesize ATP at the same rate as it is used in the highest activity of the organ. The heart is an example of such muscles, but there are many instances among skeletal muscle as well. Since in these cases, respiratory metabolism is so well developed, and is supported by an ample circulatory oxygen supply, no need arises for additional metabolic pathways like glycolysis. On

---

Dr. Mommaerts is an Established Investigator of the American Heart Association, and Associate Professor of Biochemistry, Western Reserve University, Cleveland, Ohio.

Presented in the Symposium on Recent Advances in Cardiovascular Physiology and Surgery, University of Minnesota, Minneapolis, Minnesota, September 14, 1953.

the other hand, there are muscles which function only intermittently, in periods of high activity but short duration. These are usually not well endowed with respiratory enzymes so that during intense activity the consumption of ATP far exceeds its respiratory resynthesis. Such muscles usually possess an active glycolytic enzyme system, which delays the exhaustion of the energy-rich phosphate compounds without being able to prevent it in the long run. These muscles are therefore not able to work at a high rate for unlimited periods, while in the former group a stationary balance between energy output and metabolism can be maintained. That the heart belongs in this group for functional reasons is obvious, but clearly its metabolism does not set it apart from all other muscles.

We have already referred to the fact that ATP is used in contractile activity. This important insight rests first of all upon the results obtained in the laboratory of O. Meyerhof, up to the late 1930's. As other substances such as lactic acid and phosphocreatine, became eliminated as the direct causative agents of contraction, ATP remained as the substance which, as far as one could tell, must be directly linked with the contractile process.

To cause contraction, or to provide energy for it, ATP must interact with the contractile structure which we may presume to be of protein nature. While there is a large number of different proteins in the sarcoplasm, the protein composition of the fibril is fortunately much simpler. For a time, the contractile filaments were even believed to consist of one protein only—myosin. A fundamental study by Von Muralt and Edsall (1930) revealed that this protein displays the property of flow-birefringence, which suggests that it consists of very long molecules or particles, well suited to build up a fibrous structure. Weber prepared myosin threads by extrusion into a precipitating bath of dilute KC1; these threads are good optical models of the anisotropic bands of the muscle fibril. In 1939, it was then found by Engelhardt and Ljubimova that this structure protein has enzymatic activity in that it acts as an adenosinetriphosphatase, myosin-ATPase. This was a discovery of great importance—quite independent of our eventual judgment concerning its direct physiological meaning—since it pointed for the first time to a concrete connection between energy-yielding reaction and contractile structure. The same authors as well as Needham *et al* (1942), also discovered that ATP exerts some physical effect upon myosin.

These important indications were fully explored in the classical investigations of A. Szent-Györgyi and his school, beginning in 1940. It was found, first of all, that myosin in the older sense is not a well-defined substance, but that products of highly different behavior can be obtained. dependent on such seemingly trivial details as the duration of the extraction or the degree of mincing of the tissue. Short extraction of coarsely ground muscle with 0.5 M KCl yields a product which approaches what is now known as myosin itself. This was crystallized, with some denaturation, by Szent-Györgyi, and was prepared in entirely pure form by Weber *et al*, and by Mommaerts and Parris. Myosin consists in all probability of rod-shaped molecules of 160 mμ. long, with a molecular weight which is estimated as 850,000 in Weber's laboratory and 650,000 in ours. Prolonged extraction of minced muscle, on the other hand, leads to the appearance of a complex protein, actomyosin, in which myosin is combined with actin, discovered in Szent-Györgyi's laboratory by Straub. Actin is a protein which can exist in the form of globular molecules (G-actin) or as a fibrous modification (F-actin) originating by polymerization of the globular form. In actomyosin, myosin molecules are randomly attached to the strands of F-actin, while in the muscle fibril, the two proteins apparently are arranged parallel in a highly organized structure. These same proteins also occur in the heart, but their study in this case has considerably lagged behind. Actin and myosin constitute the bulk of the contractile structure, but other proteins such as tropomyosin (Bailey) or Y-protein (Dubuisson), of unknown function, may occur in the fibrils in smaller amounts. That actomyosin is the material substrate of contractility will be documented later; in addition, its participation in contraction is also suggested by the observation of Dubuisson that it is temporarily rendered insoluble in shortened muscle.

The second important discovery by Szent-Györgyi was that both myosin and actomyosin have ATPase activity, but that only actomyosin is strongly affected by ATP in its physical behavior. The influence of ATP can be detected in actomyosin solutions by physical measurements, but shows very striking manifestations in precipitated actomyosin systems. Going from the lowest to the highest forms of organization, these actomyosin systems present the following features.

In suspension, flocculated actomyosin becomes denser, because the individual flocks contract and expell water, a phenomenon called supercontraction by Szent-Györgyi. Under some conditions, the individual flocks adhere, and the entire system shows strong synaeresis.

Threads of actomyosin contract upon the addition of ATP to one-third of the original length. The thickness decreases equally, since there is little preferred orientation in the threads, but by rolling and stretching they can be made to contract preferentially in a longitudinal direction.

Threads that contract only lengthwise, becoming thicker when shortening, and that can lift a load, have been prepared by controlled drying of an extruded thread (Weber) or by compression of actomyosin layers spread on a water surface (Hayashi).

Finally, Szent-Györgyi has introduced a preparation of fiber bundles from the *musculus psoas* of the rabbit, extracted in the cold by aqueous glycerol. This is a preparation which contains actomyosin in its original orientation without prior dissolution, but from which most other active constituents are removed in the extraction process. Such fibers likewise contract lengthwise and develop tension, and this tension is equal to the maximal tension of the muscle from which they are derived. Similar preparation obtained from cardiac muscle have been studied by Taeschler and Bing.

Last but not least, Marsh and Bendall have discovered that when such contracted fibers are treated with ATP in the presence of a water-soluble muscle protein, they can be made to relax again. In investigations by Bozler and by Goodall and Szent-Györgyi, relaxation has been obtained by means of phosphocreatine, but this too seems to depend upon the participation of the Marsh-Bendall factor, and, since phosphocreatine may phosphorylate a nucleotide retained in the fibers, it does not necessarily cause relaxation by itself.

In this series, we have arranged the actomyosin systems according to increasing perfection of their molecular organization. In the flocks and extruded threads, the actomyosin particles are unoriented and are held together by few random weak links. The better the parallel orientation obtained, and the stronger the cross linkage achieved, the more will the systems resemble *in vivo* contraction. Throughout the series, salts play a decisive role: a basic concentration of KCl is always added, while Mg promotes and Ca counteracts the contraction. One remaining discrepancy should not remain concealed: the contraction and relaxation phenomena *in vitro* are very slow, requiring minutes instead of fractions of a second, and this difference does not seem due entirely to diffusion of the ATP. We may hope that also this detail will eventually be understood; otherwise, the results will speak for themselves.

While these achievements have gone far in answering the question as to what causes and constitutes contraction, we also have to investigate how fast, by what amounts, when, and how these effects are brought about.

On another occasion, I have given some quantitative statements regarding the metabolic changes correlated with muscular work. It was found that the activation of one gram of muscle involves the breakdown of 0.25 to 0.3 μM. of ATP, and up to 0.5 μM. under conditions of maximal work. Further, it was derived that continuous activity, for example, a tetanic contraction of striated muscle, involves a steady breakdown of ATP, the rate of which depends on the type of muscle, but which may be of the order of 1 mM. per gram per minute for average mammalian muscle in tetanus, and up to about one-tenth of this for the myocardium in extreme activity. Any biochemical mechanism proposed must be in accordance with these estimates.

It is partly in the light of these estimates that I have criticized a too eager acceptance of myosin-ATPase as the *Deus-ex-machina*. The activity of this enzyme depends enormously on the pH and ionic composition of the medium—a fact which makes it very difficult to estimate its possible activity *in vivo*. But doing the best we can, the conclusion is obtained that myosin-ATPase can explain 1 to 2 per cent of the actually occurring rate of breakdown in muscular activity. This conclusion, which is largely based on the strong inhibition of myosin-ATPase by magnesium, has not been generally accepted by other workers in this field. Some o fthem point out that there are cases in which Mg does not inhibit the ATPase; even activations have been reported. But such objections have never been made in quantitative form, and it is not realized that such activation effects have hitherto been found only when the basic activity is very low, for example, at pH 7 in the absence of Ca. Our views have, for instance, been strongly attacked by Hasselbach who described that his actomyosin preparations are activated by Mg, but overlooked that his activated preparations were no more potent than our maximally inhibited ones. I maintain, therefore, that myosin-ATPase cannot be relied upon to explain the events *in vivo*.

An entirely new viewpoint has come from the study of actin. This protein has some remarkable properties, early recognized by its discoverers. While in aqueous solution, it shows no abnormal behavior, but after the addition of salt, its solution becomes extremely viscous and strongly birefringent. As mentioned before, actin occurs in the form of single globular molecules (G-actin) in water, but upon the addition of salt it polymerizes to F-actin. Recently, Straub and Laki and their collaborators showed that actin preparations contain ATP, and that without this substance actin connot polymerize. Following this development, I prepared pure actin by ultracentrifugal isolation of F-actin from a crude extract, followed by depolymerization in the presence of ATP. With pure actin, the mechanism of the polymerization reaction could be investigated quantitatively, and it was found that the following stoichiometric equation holds:

$$\text{actin} + \text{ATP} \rightarrow \text{actin}_{(\text{polym.})} + \text{ADP} + \text{P}$$

This result not only opens up the study of the mechanism of this striking molecular transformation, but has also a direct physiological consequence. For the stoichiometrical proportions are such that if all the 30 mg. actin (mol. wt. about 57,000) in one gram muscle would polymerize once, it would dephosphorylate exactly the 0.5μM. of ATP which, as calculated previously, activate one full twitch of this amount of muscle. This identity suggests strongly that the polymerization of actin is one of the elementary reactions in activity, and is possibly identical with the "fundamental process" of Gasser and Hill which precedes the macroscopically visible contraction and coincides with the initial heat production. The actin polymerization, furthermore, can be very fast, although it has not yet been possible to estimate its actual speed under conditions like those in muscle.

After these observations regarding speed and amount, we can turn to the question, "When?" referring to the problem of the sequence of events in contraction, investigated, by physical means, with such high perfection by A. V. Hill. The occurrence of polymerization of actin during the activation phase is only a hypothesis. Even the all important question of whether ATP is indeed broken down during contraction has never been decided. Encouraged by a recommendation from Hill that the relatively slow skeletal muscles of turtles should provide a favorable material in which to investigate this phenomenon, we have given considerable time to developing a method permitting the instantaneous cooling of such a muscle at any desired phase of contraction. This is achieved by high-speed immersion of a contracting and a control muscle into liquid propane cooled to 90° absolute temperature by which very rapid cooling is obtained. With this method, the sequence of chemical and structural changes is now being investigated.

There remains, then, the final question, "How?" referring to the actual molecular mechanism of the contracting process. I feel strongly that, as long as the preceding questions have not been answered, this last one is altogether too ambitious. Theories about the mechanism of contraction are, at best, fascinating intellectual exercises as long as the basic facts are not yet known.

SOME CHEMICAL ASPECTS OF THE CONTRACTILE MATTER OF MUSCLE

OLLE SNELLMAN
Institute of Biochemistry, University of Uppsala
Uppsala, Sweden

CLASSICAL HISTOLOGY provides a clear picture of the striated muscle fiber as it appears externally. A long sarcolemmal sheath contains material which displays regular striations. The histologist describes the muscle fiber as composed of repeating units of relatively isotropic bands (I) and optical anisotropic bands (A). A membrane or band Z bisects the I band and another band M bisects the A band. The finer details which can be seen using the electron microscope will not be discussed here.

The complex architecture of the cross striated muscle and its alterations in various physiological states has led to many theories about the localization of the different substances in the bands. The interest in this question is due to the fact that the visible alterations are considered to furnish clues regarding the contractile mechanism. Muralt and Edsall[8] tentatively suggested after having demonstrated the double refraction of flow in actomyosin solutions that the actomyosin was located in the anisotropic band. Schmitt *et al.*,[5] considered from investigations on formalin fixed material that the fibrils were composed of actomyosin threads. The relative isotropy of the I band was ascribed to a lack of preferred orientation in this region or to some substance compensating the double refraction in this band. Our experiments have led to a somewhat different conclusion.

We have tried to prepare non-fixed myofibrils by using the following method.

The myofibrils were prepared from rabbit skeletal muscle which were minced in fairly large pieces in a cooled mincer. A cooled isotonic buffer solution was added and the minced muscle was ground in a cooled mortar. The mass was suspended in more cooled buffer solution and centrifuged for a short time. The precipitate was discarded and the particles in the supernatant solution were spun down in the centrifuge and resuspended in cooled isotonic solution.

Investigations with a common light microscope showed that the solution contained ribbon like particles with the characteristic cross striation in a fairly pure state which also was shown by an inspection in the electron microscope. The figure shows a bundle of such fibrils at low magnification. No staining has been used. The white bands are the anisotropic ones. From the picture it can be seen that the electron scattering mass is far greater in these bands than in the isotropic bands. This is an indication of an uneven distribution of material. The different bands had about the same length 4μ showing that the contraction must have been small. When a small amount of ATP was added, they contracted violently. I think that they can be considered as part of the structural elements of the muscle.

The following analyses have been made on these fibrils. When they were suspended in 0.5 M KCl for a short time nearly all of the isotropic bands went into solution but the anisotropic bands remained. An inspection in the electron microscope showed that generally little of the material in the isotropic bands was left. From the appearance of the material in the anisotropic bands it could be recognized as being F-actin. It was also found possible to bring into solution the remaining anisotropic bands either by using 0.5 M KI or a pH of about 9, methods well known for bringing actin into solution.

The nitrogen ratio of the two solutions thus obtained was determined. The ratio was $N_{KI}/N_{KCl} = 1.97$. This is in rather good agreement with the result of Engström[1] using x-ray absorption measurements. He found a mass ratio of 1.8 for A/I using the sheath of the striated muscle from Chironomus larvae.

A determination of the phosphorus ratio has also been made. This ratio was 3.70. I think that all the phosphorus is not so firmly bound so this value is probably too low. The figure shows, however, that the greatest part of the phosphorus is bound in the A band. I believe nevertheless that some of the phosphorus really is bound in the I band too, probably as nucleoprotein, the latter conclusions is arrived at in terms of ultraviolet absorption measurements.

Presented in the Symposium on Recent Advances in Cardiovascular Physiology and Surgery, University of Minnesota, Minneapolis, September 14, 1953.

Our results indicate that the actin together with the greater part of the phosphorus is in the A band in the resting state. During the first phases of the contraction the substances move (probably the actin[13]) and unites. An indication that such is indeed the case follows from the fact that on raising the temperature of the fibril suspension the formerly KCl soluble substance no longer goes into the solution on short KCl treatment. This behavior could be accounted for if actomyosin were formed under such conditions.

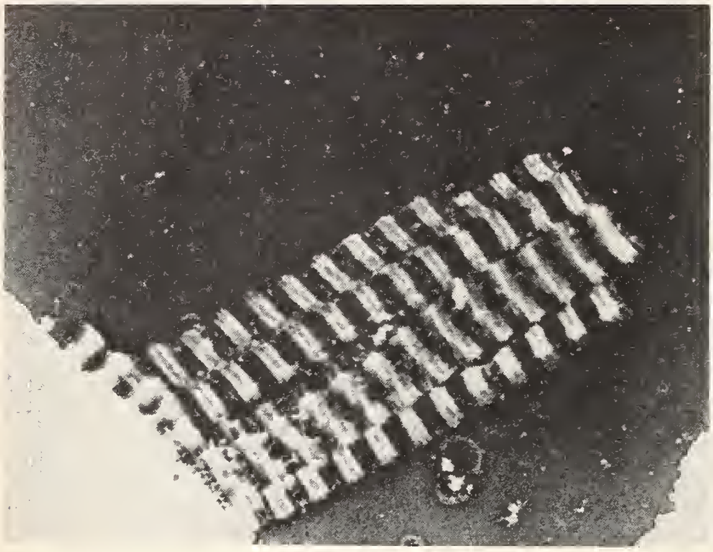

Fig. 1. Electron micrograph of a bundle of muscle fibrils. No staining (x 2 600).

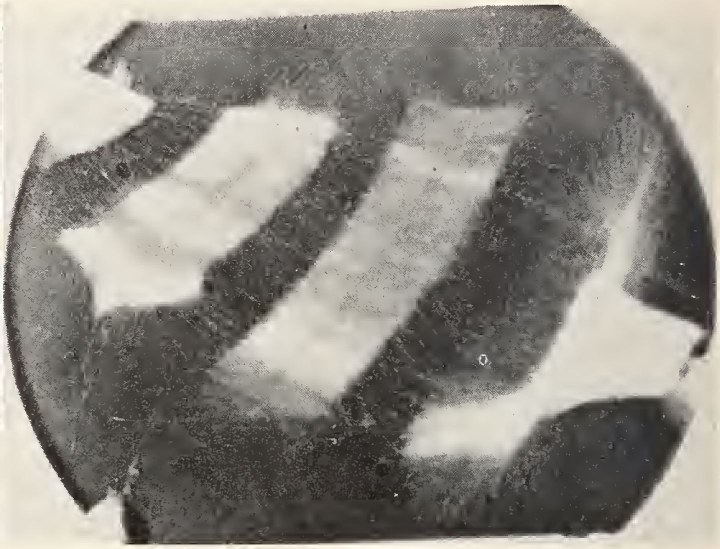

Fig. 2. Electron micrograph of an extracted muscle fibril. The isotropic band extracted with 0.3 M HCl. Gold-manganine shadowed (x 7 200).

In the case of the skeletal muscle the greatest part seems to be myosin in the I band even if, as is probable, some other substances also occur. In such a case, chiefly, actomyosin is built up during the contraction process which in turn probably then reacts further.

Up to the present time heart fibrils have not been investigated extensively. They are more difficult to obtain in a pure state. We must therefore be a little more cautious in making statements about the nature of the substance in the isotropic bands in such tissue even if the fibrils are cross striated. From other investigations we have observed that myosin and actomyosin can only be obtained in relatively poor yields.[2] If the heart muscle is more finely divided, another contractile complex is easily extracted. This complex, we have called actotropomyosin.[11] Our investigations on that complex are, however, mainly done on actotropomyosin extracted from a gravid uterus where it predominates. Our analyses indicate that actotropomyosin is composed of actin, a protein which we have called the phosphate-absorbing protein and tropomyosin mostly as nucleotropomyosin. It may be that in the case of the heart, the isotropic band contains much of the nucleotropomyosin and the phosphate-absorbing protein in a complex. Further studies must, however, be done to elucidate the questions concerning this complex in the heart.

It seems to me that the problem of contractility is connected with structure and alterations in structure. If we want to approach the problem on a molecular level we have (during the first phases) to think of alterations in the structure of the actin. During subsequent phases in the muscle action, alterations in the molecular structure of myosin or the tropomyosin-complex, may also be of importance.

Concerning the actin it is known that it can go from the molecular state of G-actin to the associated form, F-actin. It contains ATP in the G-state and liberates one phosphate (in solution) whence it goes over into the F-state containing ADP. This reaction occurs rapidly when some salt is added to the solution. Under certain circumstances the reaction can be reversed by adding ATP. Straub[14] was the first to show this, followed by Laki[6] and Mommaerts.[7]

Schematically the reaction, following Laki, can be written: $\text{G-actin ATP} \rightleftharpoons \text{G-actin} \sim \text{P ADP} \rightarrow \text{F-actin ADP} + \text{P}$

It seems, however, very unlikely to me that only a split of the phosphate residue would take place without the energy rich phosphate bond being used in a chemically satisfying way. It is therefore unsatisfying to think that, for example, that the formation of any serine-phosphate bond in the actin plays a rôle. Such a bond as it occurs in casein, is too stable.

It is more probable from the general behavior of ATP that a certain substance in the actin reacts with the energy rich phosphate and in that manner raises the actin up to a more reactive level. Also in this reaction divalent ions ought to take part as is usually the case when ATP participates in a reaction. This is also indicated by the fact that the reaction is inhibited by chelating agents.

We have tried for a long time to find in the actin the substance responsible for the reaction. I think now that Dr. Gelotte,[3] during his last time in my laboratory brought evidences for the existence of a substance (X) of low molecular weight nature in the actin. He succeeded in isolating it from purified F-actin by repeatedly shaking it with water and chloroform. In the first water extract, adenine nucleotides and sometimes even hypoxanthine derivatives are obtained in large part. The adenine derivatives are loosely connected with the actin and it is also possible to get rid of them before the experiment. Later on the prosthetic group of the actin appears. It is thus much more firmly bound. The adenine nucleotides are bonded to the actin in much the same way as a substrate molecule is bonded to the special surface of an enzyme. It may be mentioned at this point that the actin contains between 1 to 2 per cent of the new substance calculated on the basis of dry weight.

We have not as yet been able to prepare the new substance (X) in quantities sufficient to enable a determination of its constitution. It has up until present time given much trouble during our investigations because it appears in several forms. Some of them are obviously associated forms. They have also different ultraviolet spectra and can be transformed reversible one into the other. One form, which we think is a kind of monomeric form, has the ultraviolet spectrum given here. Another form can be prepared unassociated with any ions and that form has no maximum in the ultraviolet up to 210 mμ.

Obviously the presence of divalent ions in the substance (X) plays an important role in its reactivity. When possessed of its ions it spontaneously reduces silver nitrate. On the other hand, however, when devoid of its ions or if heated up to boiling point in solution prior to silver nitrate treatment, it cannot reduce it. From the infra-red spectrum it can be concluded that it contains labile carbonyl and amine groups and that it is not an aromatic compound.

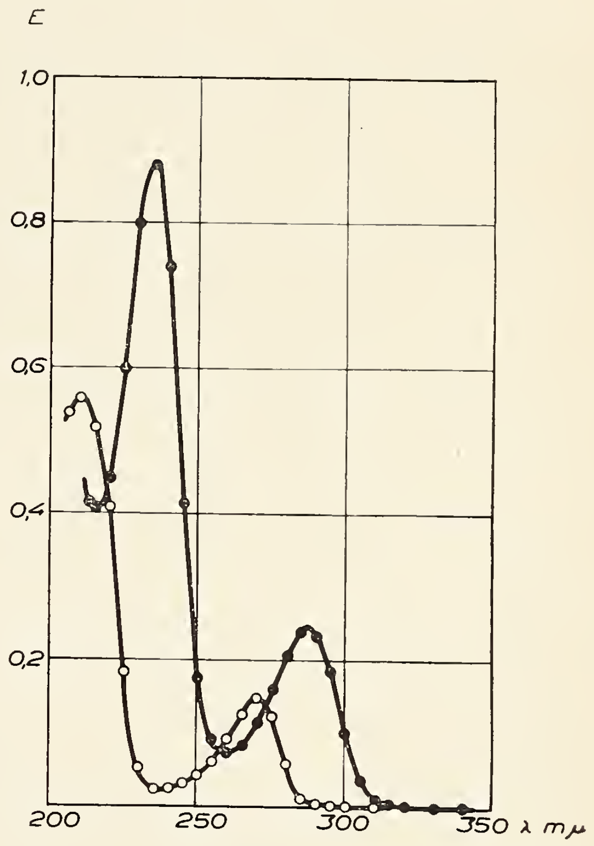

Fig. 3. Ultraviolet absorption curve for the substance (X).
Open circles: in 0.01 M HCl.
Solid circles: in 0.01 M KOH.

These investigations should give a clue to the dependence of the actin on its divalent ions and on energy rich phosphate when they are finished.

The reaction of the actin seems, at the present time, to be peculiar in many ways. One actin molecule reacts with ATP as an enzyme but at the same time it can react with other actin molecules going over to an associated state that is not enzymatically reactive as a phosphatase. This probably depends on the manner in which the reactive substance (X) is bound to the actin. However, with some alterations in the bonds it can be supposed that the actin can act only as a phosphatase.

In this connection I want to discuss another protein which we have found, and which may be derived from the actin in just such a manner. It is the phosphate-absorbing protein that has been prepared from the heart[4] and from the uterus,[12] and is connected with the actotropomyosin complex. I am inclined to consider it (in the free form) as a partly denatured protein but even so it shows some interesting properties. It contains about 10 per cent nucleotide material originating from derivatives containing the substance (X). We consider it, therefore, as derived from the actin. The protein takes up phosphate but only from ATP. It does not associate as actin does.

This phosphate uptake from ATP is probably a residue of its former phosphatase activity which is lost during its preparation. Actually when newly prepared it has a very rapidly lost phosphatase activity. When this protein is in the actotropomyosin it obviously acts as a phosphatase together with the nucleotropomyosin while this system reacts quite as actomyosin. On addition of ATP to an actotropomyosin solution and spinning down the actin the phosphate absorbing protein is found with the nucleotropomyosin in the supernatant.

When preparing the nucleotide material from the phosphate-absorbing protein there was one component of special interest which comes out from the ionic exchanger as one sharp peak containing some phosphorylated compound. A paper chromatograph was made on this using amyl alcohol-phosphate buffer. There could be distinguished six different spots with R_f-values of 41, 49, 57, 64, 69, 78. The spectra of them indicate that they can be related in the same sequence to guanine, xanthine derivatives, hypoxanthine, two derivatives which resembles guanosine and inosine and at last one uracil derivative It can be mentioned that as a certain component on the anionic exchanger a phosphorylated uric acid derivative also appeared. All these derivatives of oxy pyrimidines and purines seems to have the same origin of phosphorylated derivatives with the substance (X). That such a suggestion can be made is revealed also from certain features in the infra-red spectrum from one form of the substance (X).

It seems that the transformation to hypoxanthine and the inosine resembling derivative can occur easily. I think that sometimes when hypoxanthine has been observed in solutions of the contractile matter it can have its origin from such transformations. Therefore, it is not for the moment possible to say when a real deaminase effect has been observed.

Our investigations[9] of the action of cardiac glucosides on the contractile proteins have been quite superficial thus far, for we are in the orientation phase, trying to find the right starting point for the chemical aspect of the problem. The cardiac glucosides have certainly (beside other reactions) a direct influence on the contractile element, that is, reversing the bonding of ions in the contractile system and in that manner influencing the ionic balance in the environment of the muscle fibril.

The function seems to be a regulatory one in which the reactive substance (X) is maintained in an appropriate state by adjusting its ionic bonds in a steady state condition. This view is one which must be made the subject of some future detailed study.

In fact there is already some indication that the cardiac glucosides can act in this manner. We have observed that when a fresh anionic exchanger was used we did not obtain the form of the substance (X) which we have called the monomeric one, this being true even if we started with that form. Using a resin which had been used before, this alteration did not happen. This can be related to an exchange of ions brought about by the resin. If we started with a sample of substance (X) previously treated with cardiac glucosides the monomeric form was obtained even if a fresh resin was used. It seems, therefore that the cardiac glucosides can preserve the reactive substance in an appropriate state and that it acts so when the substance (X) is coupled to protein.

In our investigations of heart actin from cattle prepared according to Straub the preparations were made some hours after the death of the animal. This actin was contaminated with actotropomyosin which was partly degraded. This so-called actin did not associate in the usual way characteristic of skeletal actin when salt was added. An investigation in the electron microscope showed that the actin had formed clusters.[10] On adidtion of cardiac glucosides it associated rapidly to F-actin. On the same kind of actin we observed on investigating the dialysis water that also hypoxanthine derivatives were given off. On using an actin solution which was treated with cardiac glucosides merely adenine derivatives could be detected in the dialysis water.

It remains to be shown how these effects are related. When the actin was treated with alcohol we got an actin solution which did not give off any hypoxanthine derivatives; nevertheless the actin did not associate unless cardiac glucosides were added.

It thus seems that the cardiac glucosides are involved in several of the reactions and that they can do this even in the very small quantities used may depend on the fact that their action is directed against one and the same substance at least in these *in vitro* experiments. We believe that this is the new substance (X) which in different states conjugated to protein can show both ATP: ase property and be transformed in any purine derivatives.

Evidently, our present observations open a path which, when sufficiently traveled, will enable us to learn something about the mode of action of the cardiac glucosides on the contractile element.

Discussion

Victor Lorber, Minneapolis, Minnesota.—How chemical energy is converted to work in living systems constitutes one of the fundamental problems of biology and medicine. The papers presented by Dr. Mommaerts and Dr. Snellman have indicated the direction which the work on this problem is taking in muscle, where it has been studied most intensively and fruitfully. Much detailed information is at hand concerning the source of the chemical energy and the form in which it is made available for work. Similarly, a plausible concept of the working machinery of muscle is emerging from contemporary studies of the contractile proteins. However, the intimate nature of the link between the two, that is, the exact manner in which the energy of the high-energy phosphate bond is applied to the work process by the contractile elements, is still largely an area for conjecture. At the moment, the most fruitful line of attack would appear to be that exemplified by this morning's essayists, who are working to complete our knowledge concerning the nature of the contractile proteins, the small molecules associated with them, and their behavior under carefully controlled conditions.

The pronounced effect of digitalis on the mechanical efficiency of the myocardium suggests that this drug may be a tool of strategic importance in studying the contractile process. Before the intimate mechanism of its action can be investigated successfully, two outstanding questions must be settled. First, the biochemical point (or points) at which it exerts its effect must be localized. Several lines of evidence suggest that digitalis influences the conversion of chemical energy to work. Conclusive proof, however, is not yet at hand. Next, it is necessary to know what chemical entities are actually responsible for the observed effect. In other words, is the biological action due to the glycoside *per se* (or a metabolite thereof), or is it the consequence of a structural resemblance between the glycoside and a chemical agent native to heart muscle? If the latter is the correct alternative, it should be possible using currently available techniques to demonstrate the presence of a digitalis-like factor in heart muscle. We are at present examining this question.

Assuming that the foregoing problems have been resolved in one way or another, it may be permissible to speculate briefly concerning the direction in which an answer to the final question may be sought. Of the various factors known to influence the activity of biological systems, that of specific ionic concentration would appear to be the most plausible one through which digitalis might operate, perhaps through a membrane effect. Finally, it may not be amiss to point out that the final solution to the digitalis problem may be materially hastened by studying the physiological function of the glycoside in the plant in which it occurs, since we now know that over a wide range of living forms many fundamentally similar problems have been solved in essentially similar ways.

REGULATORY MECHANISMS RELATING TO BLOOD VOLUME

TORGNY SJOSTRAND
Stockholm, Sweden

SCHEMATICALLY, one can compare the blood circulation with a closed pumping system, with elastic channels and a pressure pump which subsequently is filled by pressure on the pump's filling side. In such a pumping system there is an optimal relationship between the maximal velocity of the flow, the resistance and the capacity of the channel system, the liquid volume and the capacity of the pump itself. If the channel system is dilated, without the liquid volume being increased to a corresponding degree, the pressure on the filling side of the pump diminishes and thereby the filling rate also decreases. A reduction of the liquid volume has naturally the same effect. An increase of the fluid volume produces improved conditions for filling the pump, but this effect can only be made use of, if the pump's capacity is increased. An increase in the pump's capacity does not augment the effect of the system, unless the fluid volume and thereby the filling pressure of the pump, is also increased. It might seem futile to compare the circulation, which seems so complicated with its many regulatory mechanisms, with a simple pump system. However, this comparison has been found to elucidate some basic regulations of importance for an understanding of the circulation.

The peripheral part of the vascular system is adapted to the metabolically active tissue mass. Each tissue entity is provided with one or more capillaries; and as the tissue grows, the peripheral vascular system increases in direct relation thereto. Different skeletal muscles, which are used to a different degree show, however, much different capillary density; and in investigations on rats, it has been found that with physical training, there is an increase in the capillary density of the skeletal muscles, as well as of the heart musculature.[12] It looks, therefore, at least in reference to the skeletal and heart musculature, as if the peripheral blood vessel network is adapted to the metabolic rate. The blood conducting vessels appear to be adapted to the peripheral vascular bed, and their plasticity which can be observed under pathological conditions and in congenital defects, makes it probable that this part of the vascular system is adapted both to the tissue mass supplied and the functional demands.

Blood volume shows a direct relationship to body weight during development (Fig. 1). After maturity, the blood volume remains unaltered in humans, practically up to old age, in spite of the fact that the body weight increases in consequence of an increase in fat deposit. As a result thereof, the correlation of blood volume to body weight is low in adults. The same relationship can be observed in rats.[5] This relationship indicates that blood volume is well correlated with lean body mass, or rather, to the metabolically active tissue. The difference between the sexes as regards blood volume, would practically disappear, if the blood volume was correlated to lean body mass.

The blood volume does not appear, however, to be correlated with the metabolically active tissue mass in any simple fashion. If different kinds of animals are compared, it is obvious that the blood volume per unit body weight, varies to a great degree: for example, if rabbits are compared with cats or dogs, or sheep with men. Davis and Brewer[2] have also found that the blood volume increases in dogs during physical training. The blood volume in relation to body weight, body length, or calculated basal metabolism, has also been found to be essentially greater in athletes of both sexes, such as cross-country skiers, middle distance runners, cyclists, than in average subjects. In all, determinations have been done in my laboratory on about eighty athletes and the average differences found, are so large that they appear to exclude every doubt.

With physical inactivity it appears that the blood volume diminishes. Deitrick et al[3] found a lesser difference during immobilization, the determinations being done with Evans' blue dye. In a patient suffering from a fractured leg I have found a 15 per cent decrease. In pulmonary tuberculosis which predisposes to decreased physical activity, the blood volume is also less than

normal, according to several investigations. During convalescence from different sicknesses, an increase in blood volume has also been found.[11,14] The blood volume accordingly appears to be adapted, on the one hand, to the metabolically active tissue mass, but also, on the other hand, to the metabolic rate.

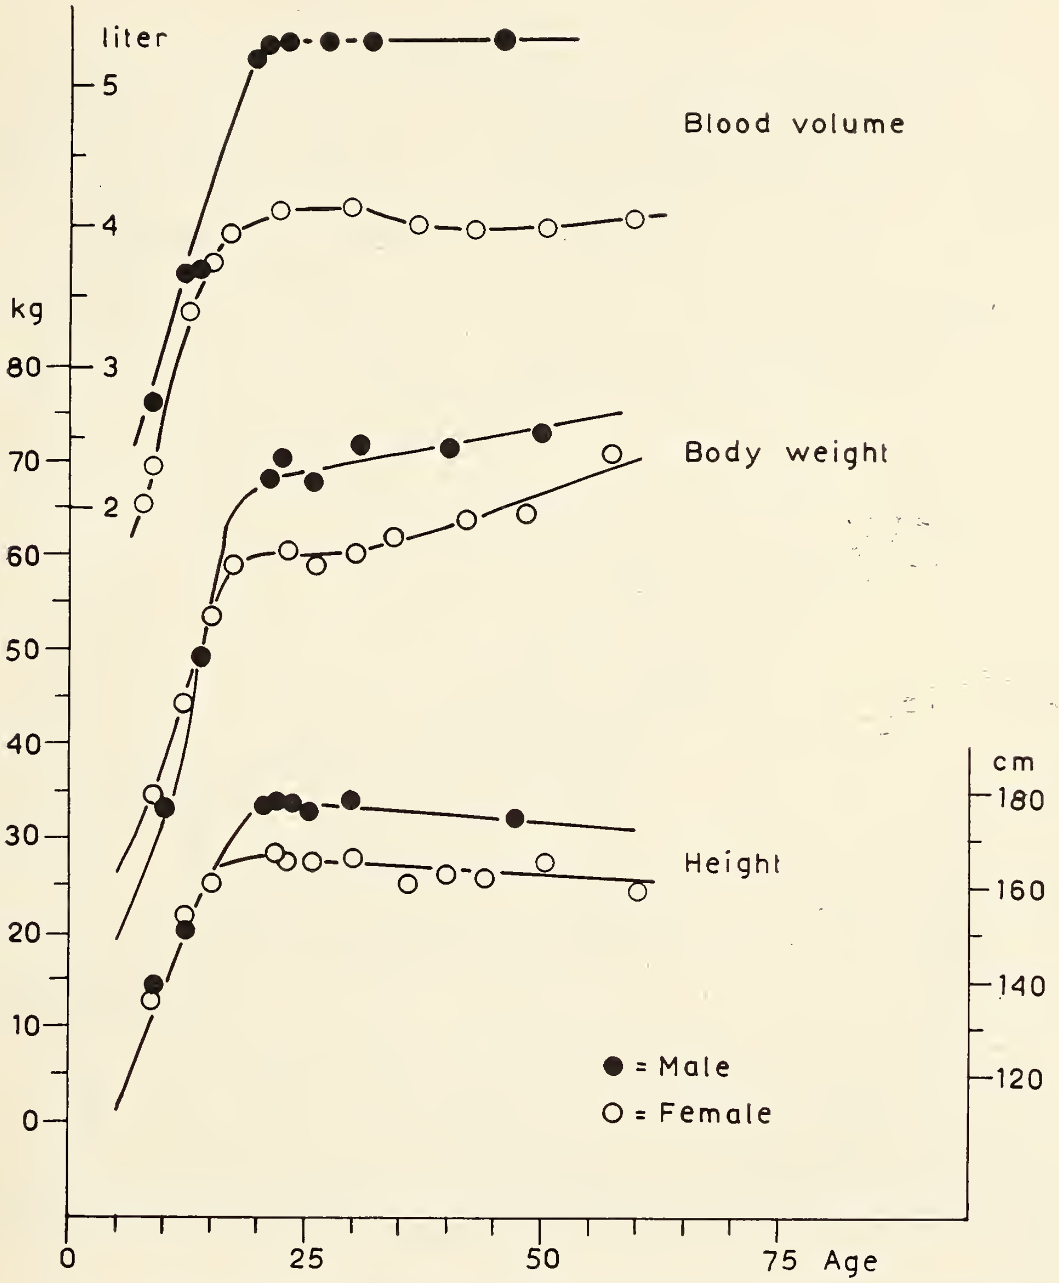

Fig. 1. The relationship between blood volume, body weight, and height and age, respectively. Each dot is a mean of determinations on at least ten different subjects.

The heart volume is greater when lying down than when standing or sitting, according to several x-ray investigations. The heart volume has been measured by x-ray photography in two perpendicular planes at the end of diastole, in the lying position, before, during and after, the effect of drugs like adrenalin, noradrenalin, atropin, nitroglycerin, digitalis in toxic doses: and it has been found that the heart volume remains unaltered or is decreased, but never becomes greater than before the administration of the drug, in spite of the fact that the stroke volume can vary essentially under these conditions. Even during arduous work on the cycle ergometer, the heart volume has proved to be somewhat less than, or the same as, in the lying position.[9] Consequently under the optimal conditions for heart filling, as exist in recumbency, the heart appears to be filled maximally with blood during diastole.

The heart volume has been shown to be directly correlated with body weight. During the years of growth the correlation is very high,[10] but thereafter lower.[8] After puberty, one finds a corresponding difference between the sexes as regards the blood volume, if one correlates the heart volume with body weight or body surface area. As is well known in physical training the heart volume increases. These variations in heart volume are conditioned, above all, by changes in the heart blood volume. The heart volume measured during life on material from men, women and athletes, respectively, has been compared with the anatomical measurement of the heart muscle volume on comparable material reported by anatomists (Fig. 2). It seems obvious from these relations, that the differences in heart volume are due chiefly to increase in the blood volume of the heart and to a minor extent to an increase in the heart muscle mass. It appears that the average thickness of the heart wall is fairly constant. The variations of heart volume with sex or physical training, appear therefore to correspond chiefly to an increase in the diastolic filling volume of the heart.

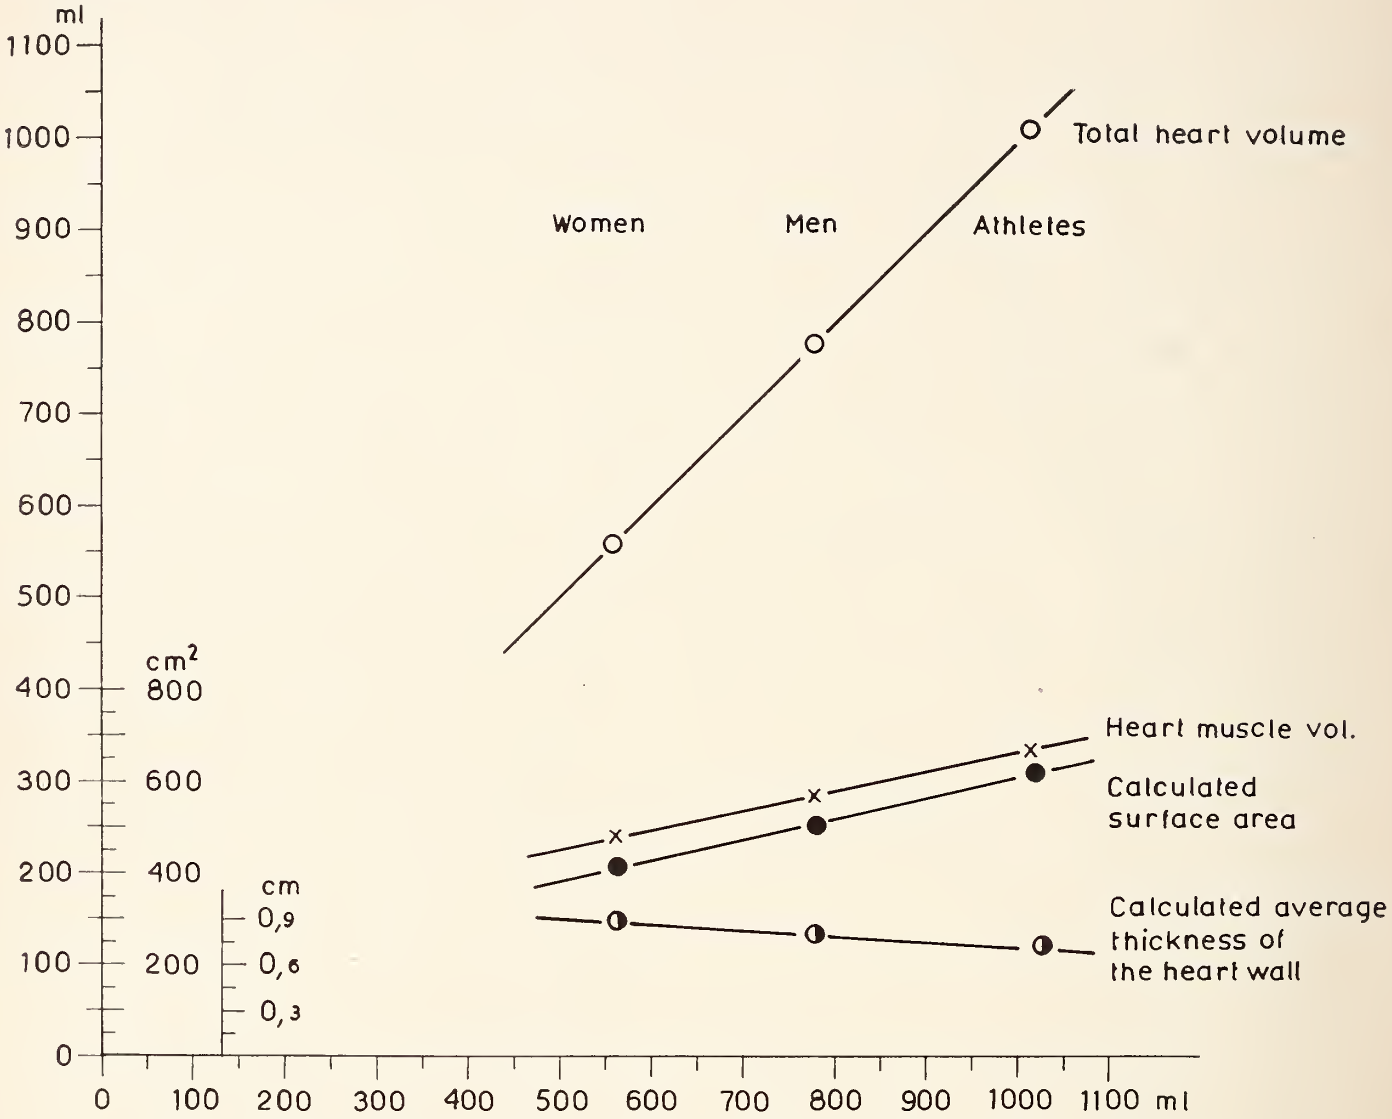

Fig. 2. The relationship between, on the one hand, total heart volume determined by x-ray during recumbency, on material composed of women, men and well-trained athletes, respectively; and on the other hand, the heart muscle volume determined postmortem on comparable material.

Now how are the capacity of the vascular system, the blood volume and the filling volume of the heart in recumbency, related to each other? By correlating the blood and heart volumes with each other, it is possible to gain an understanding of the relationship between these and the vascular system. It has been shown that there is to be found a linear correlation between blood volume and heart volume on a material from men, women and children.[8] Even in a material derived from men exclusively, but including athletes of different types, the same relation is present. Figure 3 shows the mean value for material derived from children, women, sportswomen, pregnant women; cases with pulmonary tuberculosis; average material from male subjects; and athletes of two categories, according to the degree of physical training. The values for these groups lie along one and the same regression line which shows that there is a very close adaptation of the heart's filling volume in recumbency to blood volume and capacity of the vascular system.

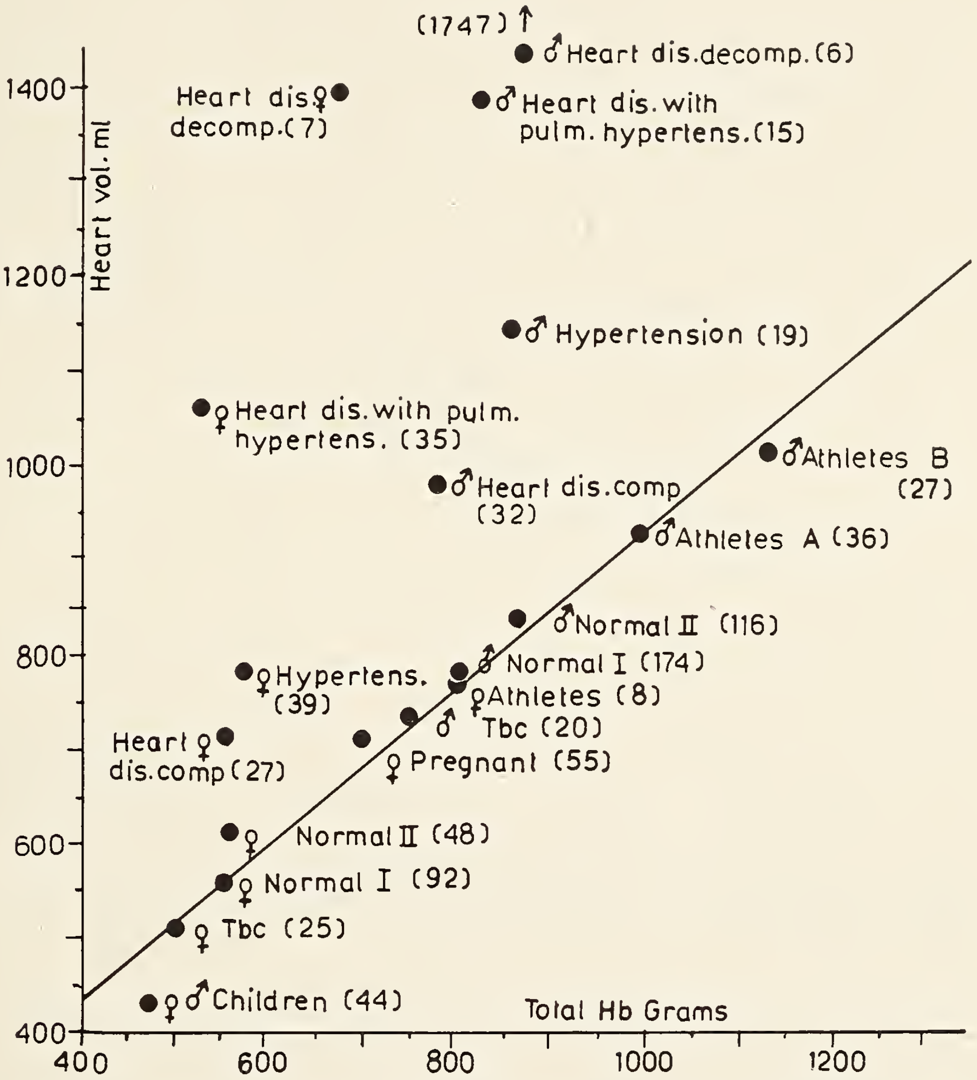

Fig. 3. The correlation between the heart volume determined by x-ray, with the subject lying down, and the total blood hemoglobin. The number of observations in each group is shown by the figure within parentheses.

How are the heart's filling volume and the blood volume related to the heart's maximal pumping effect? Adult men and women, who are made to perform work during three to five minutes on the cycle ergometer, or the treadmill until full fatigue, attain a maximum pulse rate of 190 to 200 beats per minute. Men and women attain about the same maximal pulse rate. Children reach somewhat higher values than adults, while, on the other hand, older individuals show somewhat lower values. The differences are, as a matter of fact, comparatively small. This means that the difference between individuals, in relation to the heart's maximal minute volume during work, is, for the main part, determined by the difference in the heart's maximum stroke volume. Whereas, the cardiac output increases in linear relation to the degree of the work, the pulse frequency during work stands in inverse relation to the stroke volume, and work with a pulse freqency of, for instance 170 per minute, can therefore be made use of as a relative measure of the maximum stroke volume. This work-measure is directly correlated to heart volume in the lying position and blood volume, respectively. Fig. 4 shows the correlation between work with a pulse of 170 and heart volume in material from ordinary men and women and athletes. The greater heart volume in men as compared with women, in the physically trained, as compared with the untrained, corresponds thus to the greater work performance per pulse beat. The same has been found for the relationship between the work pulse rate and the total blood hemoglobin in a material from men, including athletes, women and children.[9] There exists even a direct correlation between the blood volume and the maximal oxygen intake during exercise of short duration.[1]

Thus the maximal blood flow seems to be directly dependent upon the blood volume and the maximal filling volume of the heart. Under normal conditions these factors are adapted to each other and to the capacity of the vascular system.

It has also been shown that between the pulse frequency at rest and at submaximal work, respectively, on the one hand, and the heart and blood volume on the other, there is an inverse linear relation.[8,9] This implies that the greater the maximum stroke volume, the greater the stroke volume at any given cardiac output, independent of whether the body is at rest or performing physical work. This implies also that the stroke volume is regulated in relation to the blood volume and the capacity of the vascular system.[13]

What regulatory mechanisms can be supposed to take part in this adaptation of the vascular system, blood volume, and the filling volume and stroke volume of the heart? One can distinguish between a morphological adaptation, of the vessel wall, peripheral vessels' density, hematopoietic tissue, and heart muscle, and a functional adaptation, by way of the nervous and hormonal regulation. The latter regulation may adapt the capacity of the vascular system but may also influence the regulation of the blood volume.

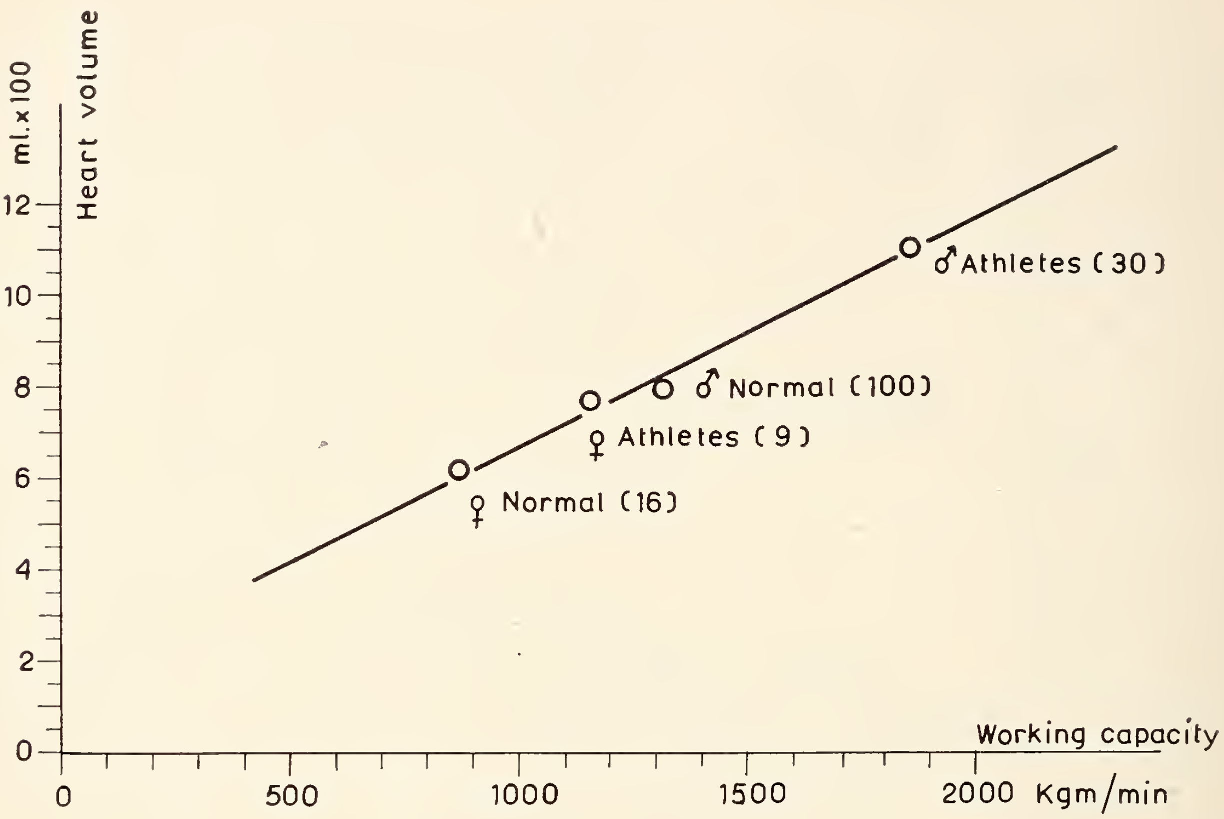

Fig. 4. The correlation between heart volume determined by x-ray and the work performance at pulse frequency 170 on average materials of women and men and well-trained athletes, respectively.

The most important primary control of the blood volume seems to occur by way of the water interchange between the extracellular space and the blood, which among other things, is proved by the fact that the blood volume after a hemorrhage is restored up to 90 per cent of the original amount in a short time. The mechanism in this case is probably, in broad outline, the following: as a result of the decrease in blood volume, the relationship between the capacity of the vascular system, blood volume, diastolic filling volume of the heart and stroke volume is disturbed; the blood volume on the filling side of the right and left heart is diminished and under unchanged conditions, even the stroke and minute volumes of the heart. These changes would initially evoke a decrease in the aortic pressure. This causes a change in vegetative control, in the sympathetic direction, which effects an increase in pulse rate and of vasomotor tone on the arterial side. The aortic pressure increases. As a consequence, the regulatory reflexes on the arterial side may not be responsible for the maintenance of the new equilibrium, and for the subsequent restoration of the original circulatory equilibrium. The stimulation for these regulatory changes may be found in the peripheral and venous parts of the circulation.

Because of the decrease in central venous pressure, coincident with the increased arterial vasomotor tone, the hydrostatic pressure falls in the peripheral vessels, which in turn causes a change in the relationship between filtration and reabsorption of water in the capillaries and so reabsorption increases. Through this the relationship tends to revert to the original state of equilibrium.

The increase in vasomotor tone on the arterial side, involves in itself only an insignificant diminution of the capacity of the vascular system, and causes a reduction of total blood flow in the body. During the first phase after a hemorrhage the adaptation of the circulation is therefore markedly depressed and there is danger of insufficiency. The dilution of the blood secondary to increased vasomotor tone, has essentially a greater importance in the restoration of the circulatory equilibrium than has the direct decrease in the capacity. If this mechanism is inhibited from functioning in consequence of an alteration of vasomotor control, centrally or peripherally, or of an alteration of the water balance, a moderate blood loss may lead to a circulatory insufficiency.

A regulation in the opposite direction has been demonstrated by investigations of Fretheim[4] on the effect of preoperative blood transfusions. If blood is given in a moderate anemia, a shift of water from the blood to the extracellular space takes place and probably secondary to this, diuresis increases. The plasma volume diminishes parallel with the increase in blood cell volume. The total blood volume remains constant. With more pronounced anemias the blood volume can even diminish through transfusion, as Fretheim observed, which is explained by the fact that the capacity of the vascular system is influenced by the oxygen concentration of the blood.

With a primary increase in the capacity of the vascular bed such as occurs during pregnancy, the heart volume as well as the blood volume increase, the latter in some cases alone, through an increase of the plasma volume.

In heart disease, the normal relationships between blood volume, heart filling volume and stroke volume are changed, often to a very great degree. The blood volume has been determined in 270 heart cases, with a well-established diagnosis, and where the circulatory relationships in most cases were analysed by means of cardiac catheterization. It was found, that in cases without stasis in the pulmonary or systemic circulations, but with a slight or moderate heart enlargement, the blood volume was lower than normal, which might be related to physical inactivity which the heart disease forces upon these cases. Heart patients who have stasis in the lesser circulation; and who on the average, had somewhat low minute volume values, showed a small increase of blood volume, especially in men. Cases with increased venous pressure in the systemic circulation, showed in the female subjects, a still more pronounced increase of blood volume. However, the greatest blood volume was found in cases of congenital heart disease with polycythemia, which cases as a rule have neither stasis nor diminished cardiac output. The vascular system can be expected to have become adapted in these cases to the altered circulatory relationships, particularly with regard to the reduction of the arterial oxygen saturation.

In heart disease, the heart volume varies to a much greater extent than the blood volume and the relation between blood and heart volumes is changed which is evident from Fig. 3. One can also show that the relationship between heart filling volume and blood volume, on the one hand, and pulse frequency during work on the other, also departs from the normal to a marked degree.

This condition of things makes possible a more exact basis for the use of the radiological determination of heart volume,[6,7] and for testing the physical working capacity which has been used in cardiological practice during the last three years. Such an analysis has been found to be of definite value, as much in establishing a diagnosis, as in evaluating different cardiac symptoms from the functional point of view.

VENOMOTOR TONE AND BLOOD VOLUME CONTROL

OTTO H. GAUER
Durham, North Carolina

IN THE PRECEDING paper by Dr. Torgny Sjöstrand, the author has presented a small portion of his comprehensive work concerned with the quantitative assessment of the relationships between blood volume on one hand and sex, geometry and activity of the body on the other hand. From his detailed measurements related to the distribution of blood volume,[11] he pointed to the fact that the size of the heart, particularly the diastolic volume, is an aliquot portion of the blood volume. The interesting observation that the heart rate at a given work output can be predicted from the available blood volume suggests that hemostatic parameters form the base on which possible response patterns of hemodynamics are laid out. In the following I want to present some of our own work, together with Dr. J. P. Henry, Dr. H. O. Siker, Dr. W. E. Wendt and Dr. J. L. Reeves, on blood volume control which throws light from a different angle on issues raised by Dr Sjöstrand.

The close relationship of blood volume to geometry and activity of the body calls for the existence of a blood volume regulatory mechanism which continuously adjusts the blood volume to the size of the vascular bed and the activity of the body. Because the size of the vascular bed depends on the state of contraction of the vascular walls, one must anticipate also a close interplay between control of blood volume and control of venomotor tone. Since von Goltz showed that the blood volume is much too small for the potential capacity of the vascular bed, many investigations have been directed towards the clarification of the mechanisms which control the tension of the blood vessels. It was, thereby, always assumed that the blood volume was constant. This assumption is not justified. During modest blood volume changes induced by hemorrhage or blood transfusions the low pressure system, in contrast to the arterial system, does not aim for constancy of pressure. When, for instance, 500 cc. of blood was drawn or infused at a rate of 300 cc. per minute, the central venous pressure varied linearly by approximately 7 cm. water per 1000 cc. Except for transient initial disturbances rapid transfusions followed the same course. There was from subject to subject surprisingly little scatter, indicating, that vascular tone of the low pressure system, as expressed by $\frac{\Delta P}{\Delta V}$ is in the normal man under resting conditions a rather constant biological parameter. Regardless of the initial rate of blood volume change, the venous pressure only very gradually returned to normal witin 3 to 4 hours.[2,4] The persistence of the hemostatic unbalance induced by blood volume changes is remarkable for two reasons. It may furnish a long lasting stimulus, influencing the dynamics of the arterial system and thereby be responsible for the peculiar behaviour of heart rate described by Dr. Sjöstrand, which would be difficult to explain on grounds of the carotid sinus receptors alone. Another even more important question is this: Does the long persistent change of pressure and volume in the low pressure system represent the adequate stim-

ulus for a volume regulatory mechanism which restores the physiological balance, not by changing the tension of the vascular walls, but by restoring the volume to normal?

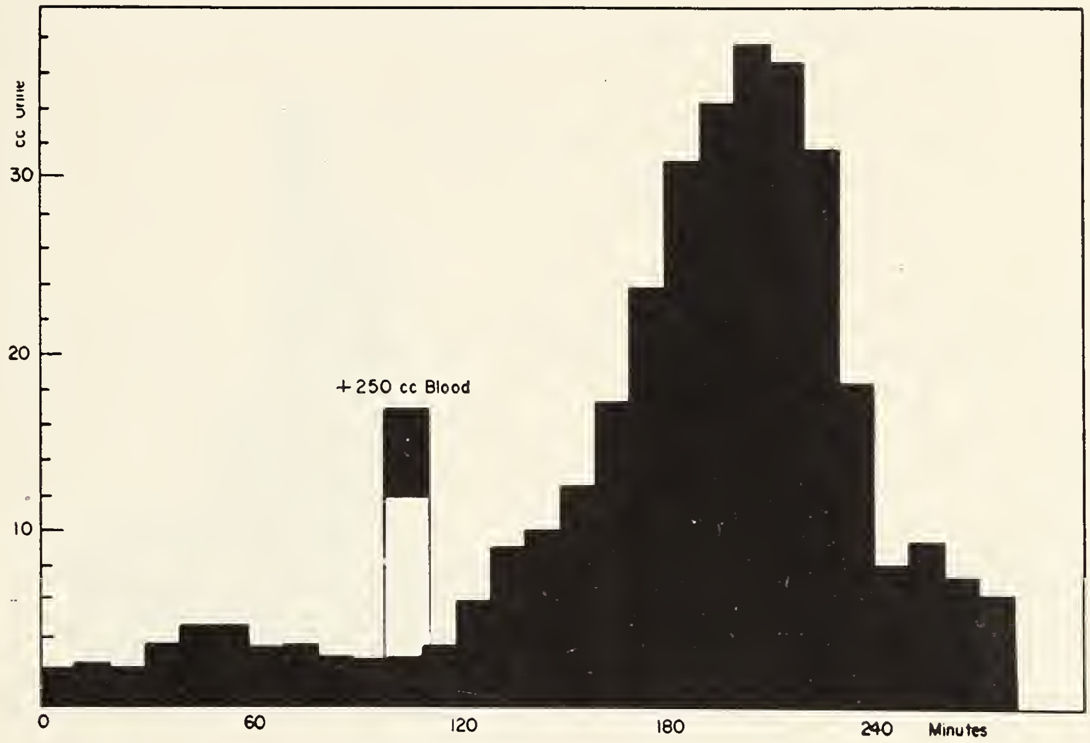

Fig. 2. Effect of a blood transfusion on urine flow in a chloralosed dog. 250 cc. of blood were infused during a period of 15 minutes.

Such a mechanism presupposes the existence of volume sensing elements either in the total circulation, or in parts of the circulation where the distensibilities are representative of the distensibility of the total circulation. While little is known about stretch receptors in the peripheral circulation, a whole variety of such elements has been described in both auricles by Nonidez.[8] Recently Paintal[9] has clearly demonstrated that the vagus carries centripetal impulses which are related to the degree of distention of the auricles rather than the pressures (Fig. 1).

Looking for an indicator organ, for a volume regulatory reflex, one has to keep in mind that final adjustments of blood volume comprise effects on blood protein formation, blood cell volume and water balance. While the first two are rather inaccessible, the excretory part of water balance could with proper precautions be used. One should expect an increase of water excretion with blood transfusion and an oliguria with hemorrhage. Figure 2 is an example of a diuresis produced by a blood transfusion which cannot be attributed to changes of the osmotic conditions or the arterial hemodynamics. It is irrelevant whether the volume increase is induced by a blood transfusion,[1] plasma transfusion,[13] or the injection of washed red cells.[12] If the concept is true, that this effect of blood volume changes on water balance is initiated by Nonidez receptors, and probably executed through the ADH mechanism, the signals being carried to the center in the vagus, it should be possible to obtain the same response of the kidney by a local distention of the circulatory organs which have stretch receptors intercalated in their walls. A slight engorgement of both auricles along with the pulmonary circulation can easily be achieved in lightly anesthetized dogs and normal humans by application of 5 to 15 cm. water constant negative pressure breathing. This procedure leads to an increased urine flow of the type of a water diuresis[5,10] (Fig. 3). Considerable strength has been added to the arguments in favor of the proposed volume regulatory mechanism by the following two observations. In dogs, the effect of negative pressure breathing on urine flow could be eliminated by vagus block.[3] Furthermore, acute inflation of a cherry size balloon, suspended in the left auricle was accompanied by a dramatic diuresis which subsided promptly on deflation of the balloon.[7] This procedure was accompanied by no change or a slight decrease of arterial pressure and an increase of left auricular and pulmonary arterial pressures of approximately 5 to 10 cm. water.

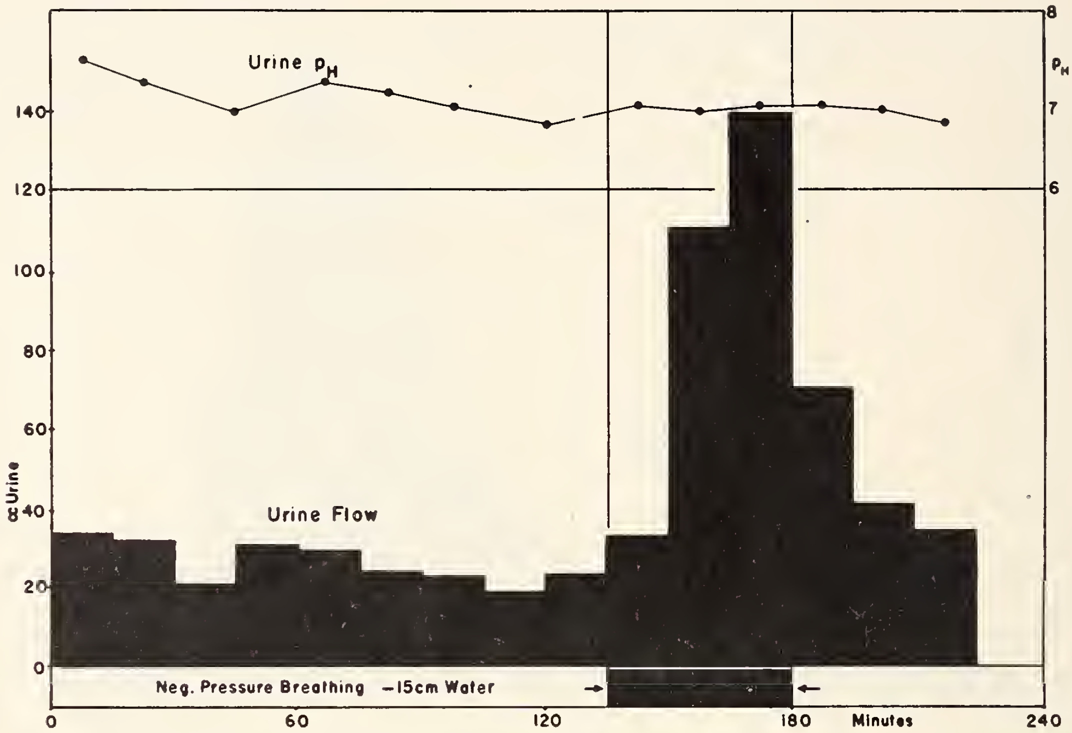

Fig. 3. Sieker et al: Effect on urine flow in humans of 15 cm. constant negative pressure breathing. Negative pressure breathing was applied for 45 minutes (heavy black band on bottom of chart).

The latter results are at variance with those of Hamilton,[6] who found retention of sodium and edema formation in dogs with induced chronic mitral stenosis. In this respect it is interesting to note, that in a normal subject all physiological events which produce a decreased filling of the thoracic pulmonary organs are accompanied by oliguria, while increased filling of the thoracic circulatory organs are usually accompanied by diuresis.[10] The great exception to this rule being congestive heart failure, tentatively leads to the working hypothesis that certain forms of edema formation may be caused by a perversion of the described hemostatic reflex for the control of blood volume.

Both this work and that of Dr. Sjöstrand converge in the emphasis of herostatics as a basic part of the functional structure of the circulation.

HEART SIZE AND STROKE VOLUME

ROBERT F. RUSHMER, M.D.
Seattle, Washington

IN RECENT YEARS, the traditional descriptions of cardiac function and control have been found inadequate for explaining many experimental and clinical observations. Commonly the heart's response has been predicted from two basic concepts: (a) that the diastolic volume is determined by the effective filling pressure,[31] and (b) that increased initial length of myocardial fibers (greater diastolic volume) causes increased energy release during the next contraction.[16] In other words, the typical ventricular response to a greater pressure, or volume load, is generally described as an increase in diastolic volume. The inevitability of this response is being questioned more and more frequently. Wiggers[28] recently emphasized that Starling's law of the heart applies only "under equal states of responsiveness" of the myocardium since the physiological state of the myocardium is changed by coronary blood supply, humoral agents and nervous actions.

The basic principles of cardiac function were originally based on cardiometer and pressure records obtained from the hearts of anesthetized, thoracotomized dogs. Controlled experiments of this type indicate the capabilities of the heart, i. e., what the heart can do under these particular experimental conditions, but they do not necessarily delineate how it responds under normal conditions. To apply these experimental results directly to normal cardiac function is to imply that the heart behaves in the same way in both normal and abnormal conditions. Obviously this is not so for many reasons, including: (a) Anesthesia unquestionably depresses neural controlling mechanisms. (b) Induced experimental loads are not the same as circulatory adjustments to normal activity; for example, increasing the volume load by elevating a reservoir of blood does not necessarily reproduce the normal adaptations to exertion. (c) Thoracotomy, as we have recently demonstrated, is generally associated with a striking reduction in heart size.[21] A typical example of this response is illustrated by the tracings in Fig. 1. The area of the cardiac silhouette diminished strikingly even before the heart itself was manipulated and the reduced size persisted in this

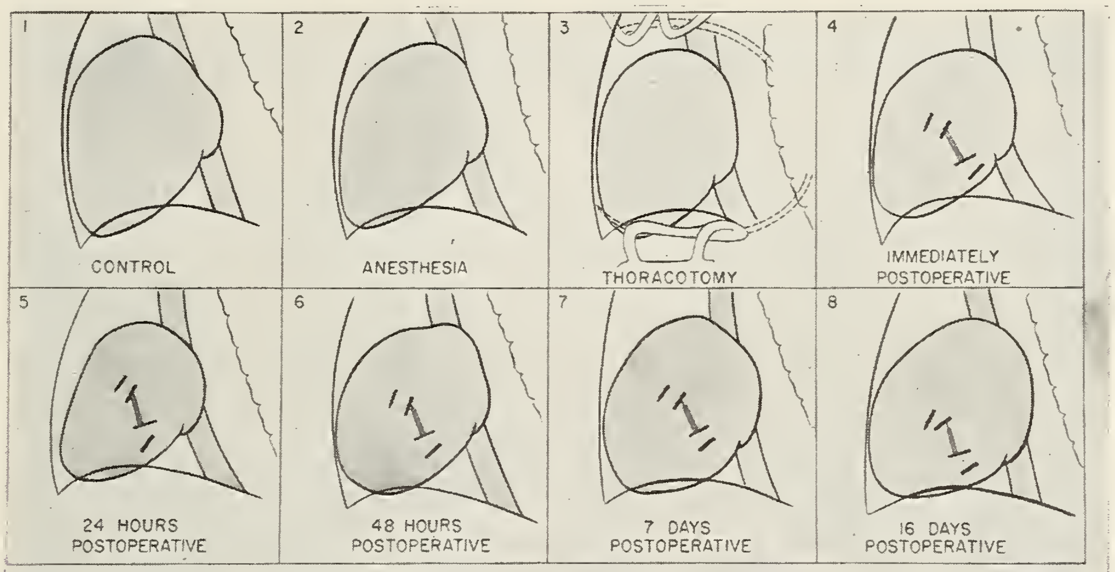

Fig. 1. Tracings of the cardiac silhouette from roentgenograms taken before, during and after thoracotomy, indicate the extent to which the heart becomes smaller when the thorax is opened. Diminished heart size persisted for more than twenty-four hours in this case, and the changes in left ventricular diameter were recorded after forty-eight hours.

From the Department of Physiology and Biophysics, University of Washington, School of Medicine, Seattle, Washington.

This investigation was supported, in part, by research grants from the National Heart Institute of the National Institutes of Health, Public Health Service and the American Heart Association.

Presented in the Symposium on Recent Advances in Cardiovascular Physiology and Surgery, University of Minnesota, Minneapolis, September 14, 1953.

instance more than twenty-four hours after the thorax had been repaired. Changes in the left ventricular area were recorded by cinefluorographic angiocardiography. When the chest was open, the left ventricle emptied almost completely during systole, but considerable quantities of blood remained at the end of systole when the thorax was intact. If the ventricles were abnormally small at the beginning of the original cardiometer measurements, greater diastolic expansion might occur because the ventricles could not get any smaller.

In the previous presentation, Dr. Sjöstrand[27] made the interesting observation that the diastolic volume of the heart of reclining humans is apparently maximal, since he and his colleagues were unable to induce any further increase in size by various drugs and maneuvers which should, according to accepted concepts, cause diastolic expansion. Relatively large volumes of residual blood in the heart of both intact experimental animals[21,23,25] and man[1,9,10,14] have been reported as has a reduction in systolic volume of the heart during exercise.[11,13] Most of these studies utilized roentgenographic techniques which do not indicate the size or volume of the individual chambers of the heart. Thus, the changes in total heart volume represent variations in the volume of any or all of the cardiac chambers. Since the atria, and right and left ventricles, differ widely in their anatomy, geometry, functional architecture and operating conditions,[22] they must be studied individually, not collectively. No method is available at present for measuring directly the absolute volume in a cardiac chamber, but a technique has been devised for continuously measuring the diameter of the left ventricular chamber in the intact unanesthetized dog.[20]

Measurements of Left Ventricular Diameter in Unanesthetized Dogs

The left ventricular diameter was recorded from variable inductance gauges, consisting of a coil 3 mm. x 15 mm., anchored to the free wall of the left ventricle, and a magnetic steel stylus anchored at one end to the interventricular septum (Fig. 2B). The gauge was installed within the ventricle under aseptic conditions by means of trochars.[20] When the ventricular walls contracted and relaxed, the stylus moved in and out of the coil. Delicate wires from the coil extended through the heart wall, between pulmonary lobes, and through the thoracic wall to the outside. The variations in inductance were continuously recorded to determine the position of the stylus within the coil. Since the thorax was open when the intraventricular gauges were installed, the very small left ventricle would barely admit the coil (Fig. 1), and the stylus was immobilized within the coil throughout the cardiac cycle. After twenty-four to twenty-eight hours, the heart had expanded to approximately preoperative size. (The marked reduction in heart size noted during operation on these dogs is in line with our previous contention that thoracotomy induces shrinkage of the heart.[21]) When the animal had recovered, changes in left ventricular diameter were measured continuously during all manner of activity including rather strenuous exertion (Figs. 2 and 3).

The cyclic changes in left ventricular diameter resembled cardiometer records except for a sharp upward deflection during isometric contraction (Fig. 3A). This deflection apparently represented a sudden increase in diameter due to a change in shape of the ventricles without a change in volume. The "end diastolic" diameter was measured at the peak of the A wave (Fig. 3A), which was produced by atrial contraction. The diastolic diameter ranged around 25 mm. The change in diameter during systole amounted to only 3 to 5 mm. which affirms the presence of relatively large volumes of residual blood within the ventricle.

The Startle Response:—The immediate response to an unexpected loud noise was a transient increase in both systolic and diastolic diameter, often followed by a sustained increase in diastolic and stroke diameters (Fig. 3C). The initial increase in diameter and the accompanying tachycardia began during the first cycle after the stimulus (Fig. 3C). We have interpreted these prompt changes in heart size and heart rate as due to neural reflexes acting directly on the heart and circulation.

The Cardiac Response to Exercise:—The first change in cardiac function during exercise was a prompt acceleration of the heart rate, and a progressive reduction in the diastolic and systolic diameters. These changes usually began immediately after the onset of the exercise, but sometimes began in anticipation of the exertion. After a few seconds, the heart rate slowed and the diastolic diameter returned to approximately the pre-exercise level while the systolic diameter usually remained smaller. Systolic ejection during exercise was generally beyond the recording range of the gauge, which blocked during every systolic interval. For this reason, it was impossible to ascertain the extent of the systolic deflection. After the exercise, both the systolic and diastolic diameters generally increased beyond and then returned to the control level. The absolute diameter changed less than was anticipated. However, relatively large changes in the volume ejected can result from small differences in the degree of filling or ejection when the ventricle operates at large dimensions. The fact that the diastolic diameters increased during startle and after exercise indicates that the ventricles were not operating at maximum diastolic volumes during the control period or during exercise. The diastolic diameter increased during a startle reaction and decreased at the onset of exercise even though tachycardia was present on both occasions. Thus, the heart rate is not the principal factor affecting left ventricular diameter.

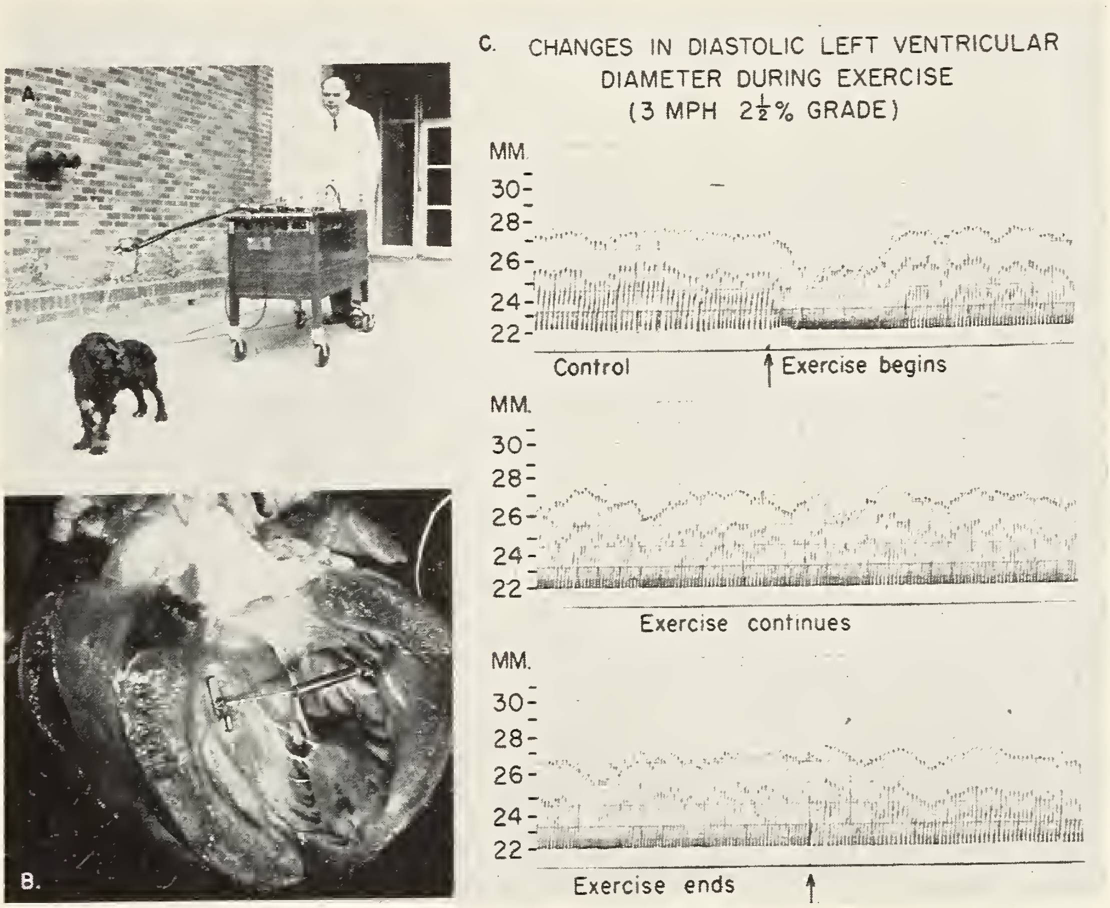

Fig. 2. (A) After recovery from the operation, dogs were exercised while running freely on a treadmill. (B) The variable inductance gauge, consisting of a coil and stylus, which recorded the changes in left ventricular diameter. (C) The initial response, to exercise on a treadmill, was a precipitous reduction in both diastolic and systolic diameters, as the heart rate accelerated. The gauge blocked with each systolic excursion during exercise indicating that the systolic diameter was less than during the control period.

These experiments represent merely the first step along an arduous path toward describing cardiac function and control in intact animals. Thus far, gauges have been successfully installed in fourteen animals. The response to exertion has been recorded forty times in four animals. Although the details of the response vary during exertion or startle, even in the same dog, the general patterns appear to be consistent. Nonetheless, data are still insufficient to derive principles of cardiac function which could be applied with confidence to other dogs or to man.

The Systolic and Diastolic Reserve Volumes

In the current experiments, the cardiac response to voluntary exertion is significantly different from the changes induced by increased venous return to exposed hearts enclosed within a cardiometer as illustrated schematically in Fig.

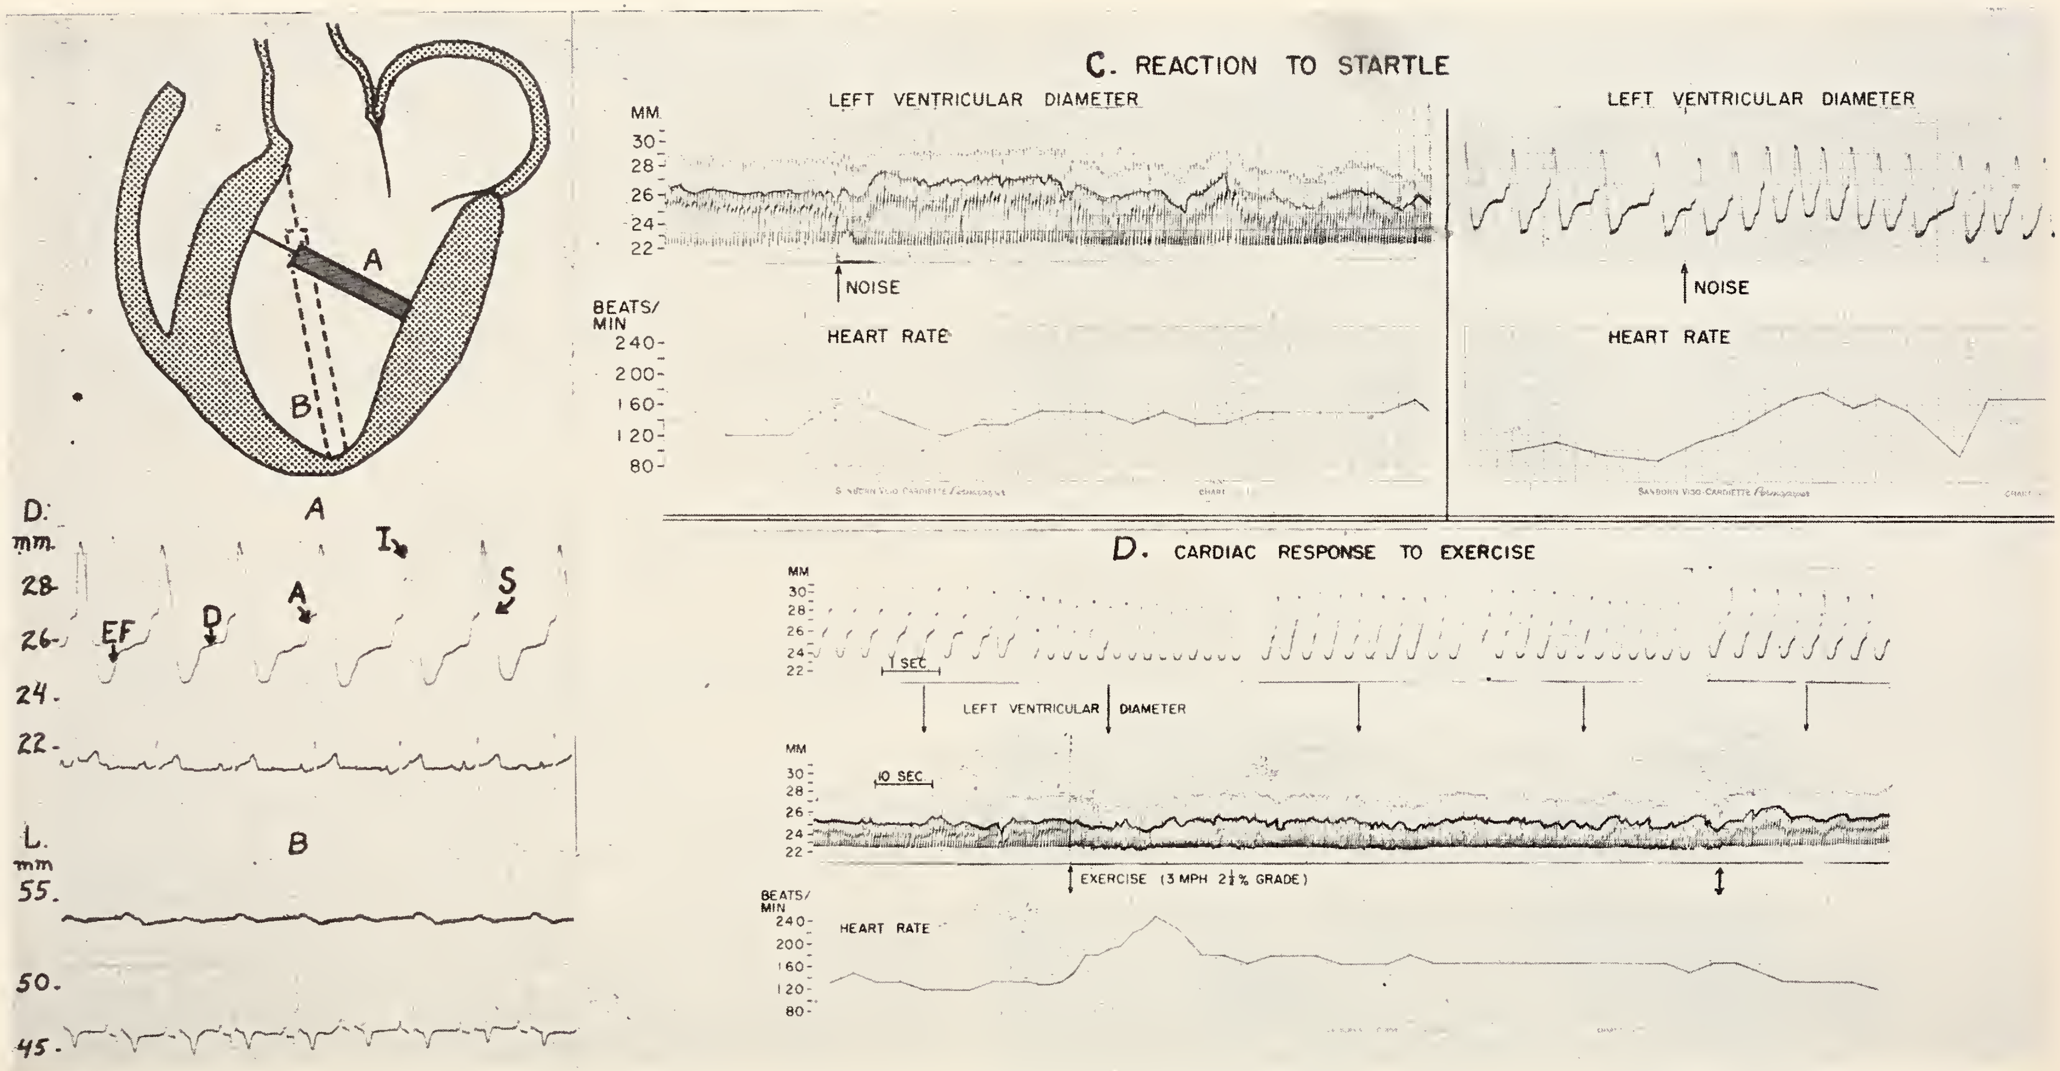

Fig. 3. (A) The changes in left ventricular diameter during each cycle consist of five phases: (EF) early filling, (D) slow filling or diastasis, (A) auricular filling, (I) isometric expansion of the diameter, and (S) systolic ejection. (B) The length of the chamber from the root of the aorta to the apex changes very little during each cycle, but the axis from the apex to the mitral valve ring shortens significantly on cinefluorographic films. (C) The response to startle is illustrated using slow paper speed (2.5 mm./sec.) on the left and the initial effects with fast paper speed (25 mm./sec.) on the right. (D) The changes in left ventricular diameter and heart rate are shown in these sample records. The end diastolic diameters at the peak of the A waves are connected by a continuous line.

Fig. 4. In cardiometer experiments, the diastolic volume, stroke volume, and systolic volumes are all increased during increased venous return (after Patterson, Piper and Starling[16]). According to the author's concept, the stroke volume of the left ventricle is increased during exercise primarily by greater systolic ejection, encroaching upon the systolic reserve volume. By utilizing both the diastolic and systolic reserve volumes (dotted lines), larger volumes of blood can be ejected during each cycle.

4. The increase in stroke volume during exercise is usually attributed to increased venous return, and increased central venous pressure producing greater diastolic distention. The current studies indicate that under resting conditions, the left ventricle is not fully distended during diastole, and is far from being completely emptied during systole. Stroke volume may be increased by more complete systolic ejection or by greater diastolic distention. For convenience, we suggest that the term "systolic reserve volume" be applied to the quantity of blood remaining in the ventricle at the end of a normal systolic ejection at rest. Similarly, the additional quantity of blood which could be accepted by greater diastolic filling might be labeled the "diastolic reserve volume" (Fig. 4). Increased stroke volume might be attained by encroaching on either systolic reserve or the diastolic reserve. Even with a constant stroke volume, the magnitude of the systolic and diastolic reserve volumes may be varied by changes in the "physiological" condition of the ventricular myocardium. We would limit the term "residual" blood to the small quantity of blood remaining in the ventricle after maximal systolic ejection. These terms correspond to those employed in describing lung volumes and have the same logical basis.

Since the left ventricle is neither completely filled during diastole nor completely emptied during systole, the factors which limit the expansion and contraction of the chamber must ultimately be established. In this way the mechanisms for increasing stroke volume might be approached more logically.

Factors Which May Influence Stroke Volume

Stroke volume is the quantity of blood which leaves each ventricular chamber between the end of diastole and the end of systole. Some of the factors which promote or impede diastolic distention and systolic ejection will be considered individually (Table I). Several of these are not generally considered in this regard and deserve attention even though the available evidence is inadequate to indicate their relative importance. Those items which might be directly affected by nervous or hormonal controlling mechanisms will be mentioned.

Systolic Ejection.—The ventricles eject blood into the arterial systems as long as the intraventricular pressures exceed the pressures in the roots of the corresponding arterial trunks. The intraventricular pressure is elevated by contractile tension developed by myocardial fibers within the ventricular wall. The ventricular walls are composed of layers of myocardial bundles, intricately interwoven and oriented in different directions. The contribution of any particular myocardial fiber depends upon its contractile tension, its anatomical position and orientation within the wall, and the geometrical characteristics of the chamber itself.[22] The right ventricular cavity is a crescentic space between the concave-convex surfaces of the free wall and the interventricular septum. The right ventricular wall consists primarily of two myocardial layers which spiral in opposite directions. Simultaneous contraction of these two layers draws the base of the heart (tricuspid valve ring) toward the apex of the heart. Any movement of the right ventricular wall toward the septum produces a bellows-like action which will displace large volumes of blood per unit of myocardial shortening. In the left ventricular wall, a thick cuff of muscles lies between the two spiral layers and encircles the cavity like a clenched fist. Changes in size and shape of the two ventricles are very different during systole. Cinefluorographic angiocardiography has shown that during left ventricular contraction, the relative decrease in diameter is much greater than the relative shortening along its longitudinal axis. Until more data are available, discussion of cardiac contraction must be restricted to general terms with no attempt to analyze the contributions made by individual myocardial bundles and layers. Thus, the stroke volume is established by the amount the various layers of myocardial fibers can shorten before the effective contractile tension is insufficient to maintain an intraventricular pressure higher than arterial pressure. Since arterial pressure is maintained within a relatively narrow range during changes in the level of activity, this factor will not be considered further.

TABLE I. FACTORS INFLUENCING STROKE VOLUME

Systolic Ejection	*Diastolic Filling*
I. Outflow Resistance	I. Effective Filling Pressure
(a) Arterial pressure	(a) Diastolic ventricular pressure
(b) Turbulence	(b) Intrathoracic pressure
II. Ventricular "Contractility"	II. Ventricular Distensibility
(a) Myocardial "contractility"	(a) Myocardial distensibility
(b) Myocardial viscosity	(b) Myocardial viscosity
(c) Law of Laplace ($P = \frac{T}{R}$)	(c) Law of Laplace ($P = \frac{T}{R}$)
(d) Interfascicular tension	(d) Interfascicular tension

Turbulence in the arterial trunks and resistance to the flow of blood through the ventricular chambers[8] represent energy waste. Energy is dissipated in many other ways as well so that only about ten to twenty per cent of the energy released by the myocardium appears as useful work: pressure and flow of blood leaving the chambers. The energy released by the heart and total work accomplished are both expressions of myocardial "contractility."

Myocardial Contractility.—No definition of "contractility" has been universally accepted. For purposes of this discussion, the term will be employed to describe the degree of myocardial shortening in relation to the work accomplished. According to this definition, ventricular myocardium, under constant or increased load, displays greater "contractility" the more completely it empties the chamber during systole. In this light, it is profitable to consider some of the factors which affect contractile tension in relation to myocardial shortening.

Contractile tension of myocardium is affected by the initial length or diastolic volume of ventricles at the onset of contraction.[28] The familiar length-tension diagram describes this relationship by a single curve indicating that contractile tension increases as the fibers are stretched up to a critical level.[5] However, fiber length is only one of many factors influencing myocardial contraction. It is well known that epinephrine increases "contractility" as evidenced by greater intraventricular pressure, faster elevation of pressure, reduced duration of systole,[29] and more complete systolic ejection.[24] Sympathetic nerves, distributed throughout the ventricular walls, discharge epinephrine-like substances which apparently have the same functional effect as circulating epinephrine.[7,17,18,19,26] The rapid reduction in systolic and diastolic diameter at the onset of exercise (Fig. 2), might well result from sympathetic discharge to the myocardial wall. Since heart rate and diameter may change in anticipation of exertion, we must not ignore the possibility that such autonomic controlling mechanisms are initiated in the higher levels of the central nervous system. It is commonly stated that tachycardia is responsible for reduced heart size. The fact that an accelerated heart rate may occur with either an increase or a decrease in left ventricular diameter (Fig. 3) suggests that these changes in size are not the direct result of shorter cycle length. It seems more likely that the factors which produce tachycardia, such as autonomic discharge, usually, but not invariably, promote increased systolic ejection by inducing increased "contractility."

Fig. 5. Some of the factors which may influence stroke volume are schematically illustrated. Each of these factors affects both diastolic filling and systolic ejection (see text).

Thus, changes in "contractility" of the myocardium represent altered "physiological" conditions of the myocardium. Therefore, the traditional length-tension curve alone does not adequately describe "myocardial contractility." Instead, a family of curves must be established to indicate the range within which the musculature may operate under varying physiologic conditions of the myocardium (Fig. 5A). This will require a great deal more investigation of myocardial activity during contraction at constant length (isometric) and with myocardial shortening during contraction. The schematic length-tension diagrams in Figure 5A represent muscles contracting isometrically. However, muscular contraction without shortening can perform no external or useful work.

Myocardial viscosity is a term used by Lundin[12] to describe a pronounced drop in contractile tension which occurs when myocardial strips shorten during contraction. Viscosity effects in contracting muscles have also been observed by other investigators.[2,6] During isometric contraction, myocardial fibers develop high tension rapidly and sustain it well during their contraction. In contrast, if the muscle shortens rapidly after the peak of isometric contraction has been reached, the tension falls off abruptly even though contraction continues. The drop in tension is increased as the rate and extent of shortening increases so that with extreme shortening, contractile tension approaches resting tension. The term "viscosity," as applied to this phenomenon, indicates that the loss of tension is probably due to "friction" within the myocardial fibers as the contractile elements are rearranged during a sudden change in length. Since the ventricles cannot eject blood without shortening of the myocardial fibers, this drop in tension assumes great importance in cardiac function.

The larger the diastolic volume, the less the myocardial fibers must shorten to eject a particular volume of blood. Both the rate and extent of myocardial shortening are reduced when the ventricles contract from large diastolic volumes. The loss of energy required to overcome internal friction (myocardial viscosity) is similarly diminished by diastolic expansion. Thus, the contractile tension, and the work accomplished per unit of energy released (efficiency), are theoretically increased when diastolic volumes are large and the initial length of myocardial fibers is relatively great. If nervous or hormonal influences could reduce viscosity, this effect would be another mechanism for direct neural control of "contractility."

The Law of Laplace.—The pressure within a hollow cylinder is maintained by tension in the walls. The amount of tension required to support a particular pressure is proportional to the radius of the cylinder.[4] The relation between the pressure (P), the wall tension (T) and the radius of the cylinder (R) is expressed by the formula: $P = \frac{T}{R}$ (the law of Laplace). A partially inflated, sausage-shaped rubber balloon illustrates the principle.[32] During the initial inflation, considerable pressure is required to produce any distention. When one portion of the balloon begins to distend, further inflation is much easier. At the stage illustrated in Fig. 5C, the inflated portion has a large radius; the wall is very tense and resists indentation. The portion of the balloon with a small radius supports precisely the same pressure, but the walls are relatively flaccid and readily compressed. In this case, the pressure is constant throughout the balloon and the wall tension is directly proportional to the radius.

If the left ventricle is considered a cylinder[25] surrounded by circularly oriented fibers (the deep muscle bundles), the tension in the myocardial fibers required to sustain a particular level of intraventricular pressure is greater when the ventricle is distended than when it is more completely emptied. If all myocardial layers developed the same tension, the inner layers of myocardium would be more effective in elevating intraventricular pressure than the outer layers.[22,25] If the myocardial fibers sustained the same tension during shortening, the intraventricular pressure could rise progressively as the ventricle emptied. Actually, the tension lost during myocardial shortening is compensated to an unknown extent by the decreasing radius described by the myocardial fibers as the chamber is emptied. The spiral muscle layers in the right ventricular wall describe a circle of very great radius and would have to develop extremely high tension to produce right ventricular pressures as high as the normal left ventricular pressure.

Interfascicular Tension.—Obviously the degree of myocardial shortening is not the same in different myocardial layers. The internal circumference of the left ventricular wall is the most reduced; the outer layers of circularly arranged fibers shorten to a less extent and the superficial spiral muscles shorten least of all. The various muscle layers are entwined and interconnected. If one layer contracts more than the other during systole, stress is applied to the connections between them.[22] This might compress the inner layers of the left ventricular wall as in Fig. 5D.[3] The various myocardial layers are oriented in different directions, schematically represented by a basket work in Fig. 5D. If the fibers in these two layers are connected together and all shorten simultaneously, tension will develop in the connections between them. These two forms of stress in the connections between muscle bundles have been termed "interfascicular tension."[22] The energy of contraction expended in placing these connections under tension is wasted so far as systolic ejection of blood is concerned. Assuming that minimal tension between layers occurs at or near the normal diastolic level, the greater the myocardial shortening, the greater the interfascicular tension. Obviously then, the lesser degree of myocardial shortening in the various layers, when the ventricles function at large diastolic dimensions, also diminishes the energy wasted in developing interfascicular tension.

Thus, the extent of systolic ejection depends upon the contractile tension which is developed and sustained by the myocardial fibers as the ventricles eject blood. Myocardial tension becomes progressively more effective in elevating the intraventricular pressure as the radius of the chamber is diminished. This beneficial effect is countered by the loss of tension during myocardial shortening due to myocardial viscosity and the energy wasted as interfascicular tension. There are undoubtedly other factors, but it is clear that the ventricles derive certain important mechanical advantages by functioning at large diastolic dimensions with relatively large quantities of systolic reserve blood. The author believes that the systolic reserve volume is normally greater than the diastolic reserve as indicated in Fig. 4. Encroachment upon the systolic reserve when the ventricles accomplish greater amounts of work requires increased myocardial "contractility."

Diastolic Filling

Ventricular filling occurs in three stages when the heart rate is sufficiently slow (Fig. 3A). A major portion of inflow occurs during the early diastolic period, beginning immediately after completion of systole. The rapid filling phase ends with a relatively abrupt transition to a period during which inflow is slow or stopped (diastasis). Finally, a variable increment of blood enters the ventricle during atrial systole just before the succeeding ventricular contraction. Since space is limited, the discussion will be largely restricted to the factors which affect ventricular filling during early diastole. The volume of blood in the ventricles during diastole is determined by two principal factors: (a) The effective filling pressure and (b) the resistance to distension offered by the ventricular walls (Table I). The rate of filling is determined by the atrioventricular pressure gradient and the resistance to distension. The "effective" filling pressure refers to the combined action of intraventricular pressure and the distending influence of the subatmospheric intrathoracic pressure. If the pressure within the ventricles and central veins and the fluctuating intrathoracic pressure are considered to remain within fairly narrow limits, ventricular resistance to stretch (distensibility) is the principal limiting factor to be discussed. Distensibility is defined as the diastolic ventricular volume per unit of effective filling pressure. If the ventricle accepts a greater quantity of blood without an increase in effective filling pressure, the distensibility is increased.

Myocardial Distensibility.—When relaxed myocardium is progressively stretched, the resting tension increases, gradually at first and more rapidly as the elongation continues. The relation between resting length and resting tension was illustrated by Frank[5] as a single curve, which implies that the diastolic volume is determined by the diastolic filling pressure (e.g. distensibility is constant). Actually there is direct evidence that epinephrine increases ventricular distensibility,[15,17,24,29] summarized by Wiggers[29] as follows:

> "Restated, the diastolic volumes of the ventricles can be increased beyond their normal capacity (1) by an increase in initial pressure overcoming the inherent tendency of the ventricles to resist stretching or (2) by a reduction in this inherent power of the ventricles to resist stretching, i.e., by a reduction in their tonus. Under normal conditions the former mechanism operates; under epinephrine the latter mechanism not only enters, but predominates."

A similar conclusion was derived from measurements of left ventricular area and effective filling pressure in intact, anesthetized dogs.[24] If the diastolic volume increases without a corresponding increase in effective filling pressure, the length-tension relationship for resting myocardium must be represented by a family of curves or a range within which the myocardium functions under varying physiological states. These observations indicate that circulating epinephrine or sympathetic discharge releasing epinephrine-like substances within the ventricular walls can increase both myocardial distensibility and contractility to provide greater stroke volume by both greater diastolic filling (without increased filling pressure) and greater systolic ejection. The fact that the systolic and diastolic diameters tended to change in the same direction during exercise and startle in intact unanesthetized animals (Fig. 3) cannot be rationalized effectively with existing data.

Myocardial Viscosity.—Relaxed myocardial fibers respond to a sudden stretch by a marked increase in tension.[12] Thus, the internal friction within myocardial fibers opposes any sudden change in length, either stretching or shortening (Fig. 5B). At first sight, ventricular distension should be markedly impeded during early diastole when, in fact, the filling is extremely rapid. The sudden transition between rapid filling and slow filling might be due to myocardial viscosity, but this would mean that sudden stretch of myocardium does not occur until filling is largely complete. This possibility will be considered in relation to the effects of interfascicular tension *(vide infra)*. Diminished myocardial viscosity would facilitate diastolic filling and could be another mechanism for neural and hormonal control of stroke volume.

The Law of Laplace.—At the end of systole, the radius described by the myocardial fibers is minimal for that particular cycle. As ventricular filling begins, the effective filling pressure required to overcome myocardial resistance to stretch would be greater than at any other time during the cycle. Actually the filling rate is greatest, and the effective filling pressure is often minimal, during early diastole. It seems clear that little or no resistance to distention is offered by the myocardium during early diastolic filling. The apparent paradox between the early rapid filling, and the theoretical resistance to distention offered by both myocardial viscosity and the relation $P=\frac{T}{R}$ may be at least partially resolved by considering the interfascicular tensions developed during systolic contraction.

Interfascicular Tension.— During ventricular systole, the inner layers of the myocardial bundles are probably under compression and the connections between the various layers under tension. The energy of contraction which is dissipated in the form of interfascicular tension acts to impede systolic ejection, but is stored as potential energy until the ventricles relax. At the beginning of diastole, this potential energy is rapidly released, acting to restore the ventricular chambers toward their diastolic dimensions. Thus, interfascicular tension acts to facilitate rapid filling during early diastole and resistance to distention may be minimal during this phase. If this is true, active stretch on the myocardium due to the effective filling pressure may not begin before the transition between the rapid filling and the slow filling phases. On this basis, more complete systolic emptying would be expected to promote more rapid early filling so that tachycardia would be less likely to encroach on the rapid filling period. This prediction has not yet been confirmed.

Summary

The heart is generally believed to respond to an increased pressure or volume load by distending to greater diastolic volume. This concept is based on experiments conducted on anesthetized thoracotomized dogs in which the heart is characteristically much smaller than under normal conditions. Direct recordings of left ventricular diameter of intact unanesthetized animals demonstrate that during exercise, diastolic diameter did not usually increase. Instead, the systolic diameter appeared to be reduced. Both diastolic and systolic diameters are increased after exercise and after an unexpected loud noise. On the basis of these experiments, it is proposed that stroke volume can be increased by utilization of either the diastolic reserve volume or the systolic reserve volume. Rapid changes in ventricular diameter from cycle to cycle suggest direct effects of neural reflexes on myocardial "distensibility" and "contractility." Some of the factors which influence

ventricular "distensibility" and "contractility" were considered with particular emphasis on possible mechanisms for neural control of stroke volume.

SYSTEMATIC ERRORS IN FLOW DETERMINATIONS BY THE FICK METHOD

R. W. STOW, Ph.D.
Columbus, Ohio

IN MANY PHASES of cardiovascular investigation, it is essential to make measurements of the rate at which blood flows through an organ. The mounting demand for precision in quantitative physiology causes us to develop new methods of measurement, and to re-examine the accuracy of long-accepted methods. For many years the application of the Fick principle has provided the classical indirect means of measuring blood flow. Other methods have been judged on the basis of their agreement with Fick measurements. Careful workers have recognized the importance of "the steady state" as a prerequisite to reliable determinations. However, either "the steady state" has escaped rigorous definition, or at least the definition has not been widely appreciated.

Until recently, apparently few doubts have been entertained regarding the validity of the conventional application of Fick's law. Lately provocative articles have appeared in the literature which should stimulate a reconsideration of the assumptions underlying the Fick method of determining cardiac output and of the justification for making these assumptions.[2,7]

First, several questions can be asked concerning the usual application of the Fick principle; second, the lines can be indicated which future experimentation might take to throw light on unanswered questions. The discussion may proceed by examining a statement of Fick's law in several forms, and by describing a model to which the law unambiguously applies. The difficulties that obtain in applying the principle to the real physiological system will be demonstrated by considering the discrepancy between the ideal model and its physiological counterpart.

The law of Fick states that the rate of uptake of a reference material by an organ must equal the net rate at which the material is removed from the organ by the blood flowing through it (other paths of removal being excluded). The statement is conveniently expressed as an equation:

$$\frac{dM}{dt} = F_oC_o - F_iC_i,$$

where $\frac{dM}{dt}$ = rate of uptake of reference material by organ in question
F = rate of blood flow
C = concentration of reference material in blood
Subscripts
$_i$ and $_o$ refer respectively to blood flowing into or out of the organ

This form of the law is applicable to infinitesimal intervals of time, and since means are not available for instantaneous measurement of uptake and blood contents, the equation as it stands is not in a usable form. Uptake and blood contents are measured over an extended period. Thus, in practice, the integrated form of the equation (second equation) is employed.

$$M = \int^{T} (F_oC_o - F_iC_i)\, dt$$

If the rate of flow, F, and the concentrations of the reference material in the blood supplying and draining the organ are independent of time: i.e., constant during the interval of observation, T, these terms may be taken from under the integral sign and the equation reduced to the following simple statement. During the observation the uptake of reference material is equal to the product of: the rate of blood flow, the arteriovenous difference in the concentration of the reference material, and the time interval involved. The equation is then:

$$M = F(C_o - C_i)T$$

In order to arrive at this simplification it was necessary to assume that the flow and concentration were constant. Also, it may be emphasized that the assumption is implicitly made that the measured uptake reflects the net amount of reference material added to the blood flowing through the organ. This is the familiar form of Fick's law which is used for the calculation of flow from these data. In the restricted area of the appli-

From the College of Medicine, Ohio State University.

cation of the law of Fick to the determination of flow, it might be asserted that the "steady state" is one in which this usable expression of the principle may be applied without error.

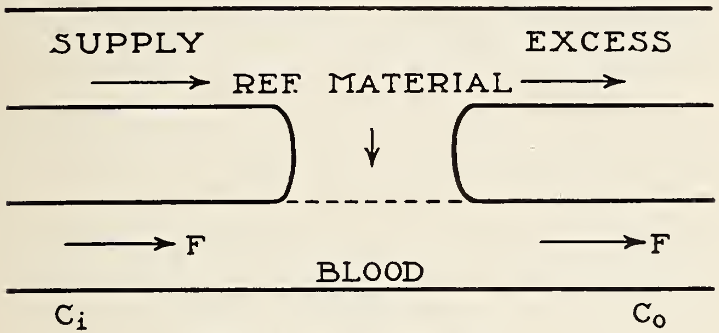

Fig. 1. Idealized organ.

In Figure 1 is shown a simple model which would strictly conform to the restrictions imposed by the assumptions made in deriving the last equation. The essential features are: (1) vessels supplying and draining the organ, (2) a supply of reference material to the organ, (3) a "dead space" or reservoir in the organ of fixed volume both for blood and for the reference material, and (4) constant blood flow and blood concentrations during an observation.

In the actual case, for instance in determining cardiac output by the pulmonary transport of oxygen, it is obvious that these conditions are by no means fulfilled. The cardio-pulmonary system is much more complex than this simple idealized model. In principle, the physiological system is represented in Figure 2, which illustrates some of the pertinent details by which it differs from the simple model.

Under the influence of the cardiac cycle, the respiratory cycle, and from other causes, the lung volume and the pulmonary blood volume change. It is well known from the work of various investigators; for example Greene and Swanson,[3] and Heymans and Jacob,[4] that as a perturbation to the basic respiratory excursions, the mean lung volume undergoes considerable periodic fluctuation with a period equal to several respiratory cycles. Plethysmographic studies indicate the existence of cardiac, respiratory and relatively long term fluctuations in the volume of the extremities. These are consistent with the notion that the pulmonary blood volume undergoes periodic change.

Since in practice the oxygen uptake can only be measured at the mouth or nose, the variable buffer capacity for oxygen of the alveolar space and the pulmonary blood may interfere with the accurate short term measurement of the uptake as referred to the blood flowing to and from the lungs. This question has been raised by Fishman and his colleagues.[2] In order to avoid this type of error it is essential that the amount of oxygen within this buffer reservoir be the same at the beginning and at the end of the period of observation.

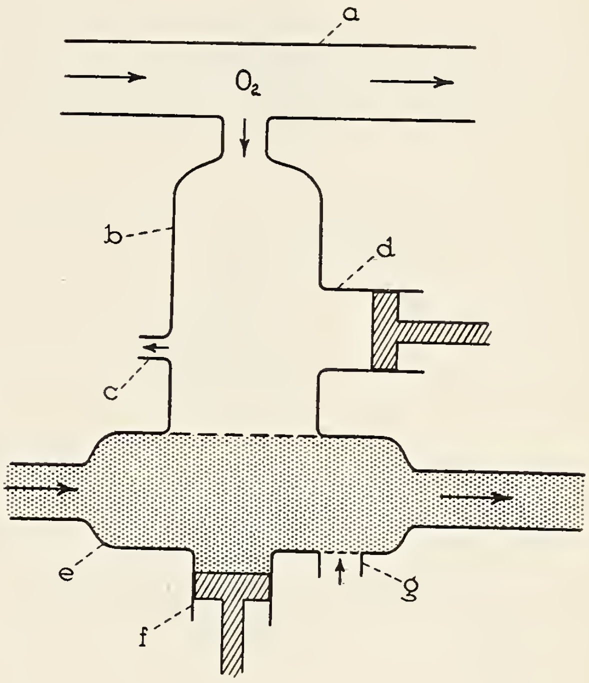

Fig. 2. Schematic representation of cardio-pulmonary system. (a) external airway, (b) total lung capacity, (c) route for direct nonvascular pulmonary, consumption of oxygen, (d) variable part of lung capacity, (e) central blood volume, (f) variable part of central blood volume, (g) drainage of venous blood to left ventricle, through Thebesian veins.

Recently, Drs. Visscher and Johnson have initiated consideration and discussion of another important aspect of the total problem.[7] They have pointed out that the usual procedure of sampling blood at constant rate may not yield a sample of the same oxygen content as the average content of all the blood which flows past the sampling site in the collection period. This undesirable situation can occur whenever both the rate of flow and the oxygen content of the blood, passing the sampling site, vary during the sampling procedure.

While this error is *per se* a sampling error, the circumstances of variable flow and concentration, which give rise to it, may also impart an error directly referable to the discrepancy between the ideal model and the real system. For, the buffer reservoir of the central circulation and lung volume may temporarily absorb, or give up, oxygen, even without an alteration in its volume if the concentration of oxygen in the blood or gas in this space undergoes fluctuation. This factor could be expected to contribute a systematic non-random error in the period of changeover from one "steady state" to another, as for instance, in the transient period of adjustment to exercise or to an alteration in the inspired oxygen tension.

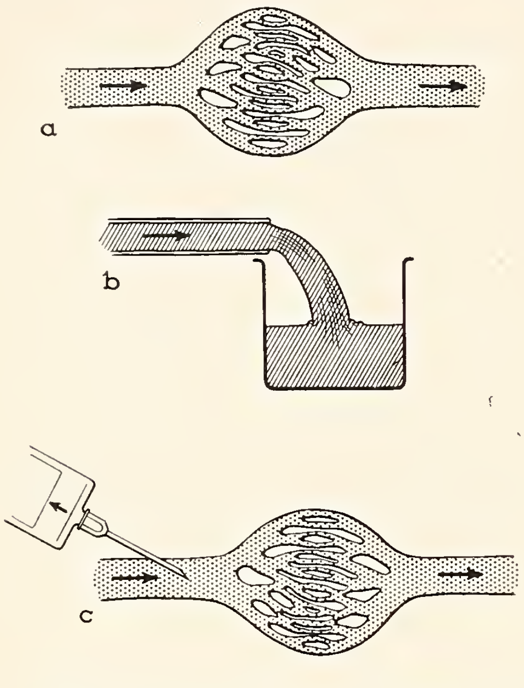

Fig. 3. Hypothetical and actual methods of sampling blood supplying an organ under investigation. (a) the organ with its artery and vein, (b) the hypothetical collection of blood for an arterial sample, (c) the actual collection of an arterial sample in a syringe.

To return to the sampling error, its basis can be understood by considering in detail the relation between the collection of the sample and the flow of blood and of oxygen past the sampling site. In Figure 3a, the organ in question is illustrated with the artery and vein which serve it. Focussing attention on the blood in one particular vessel, the flow in the artery may be examined. If, without disturbance, the artery could be severed and the blood flowing through it caught in a beaker for the same length of time that the sampling procedure would ordinarily require, after this interval the beaker would contain the same volume of blood and the same amount of oxygen as otherwise would have entered the organ. This hypothetical procedure is shown in Figure 3b. This would be true regardless of variations in flow or oxygen content during the collection. The average content of the blood in the beaker, multiplied by the volume of blood, would equal the quantity of oxygen which would have entered the organ in the collection interval. It is precisely this concentration that is required in the calculation of blood flow from the simplified equation expressing Fick's law for extended periods of time.

In actual practice a needle or a catheter is inserted in the artery and blood is withdrawn at approximately constant rate (Fig. 3c). In the presence of variable flow and oxygen content, the average content of the sample thus obtained might not be the same as that of the blood in the beaker. The discrepancy between the two occurs due to the fact that the flow into the syringe, , *is not* always proportional to the flow in the vessel, F. The syringe sample would yield the *time average concentration,* whereas the sample from the beaker would have the *volume average concentration.* The time average concentration is equal to the quantity of oxygen in the syringe divided by the volume of blood in the syringe. The equivalent equation is:

$$\overline{C^t} = \frac{\int^T \mathcal{F} C dt}{\int^T \mathcal{F} dt} = \frac{\int^T C dt}{T}$$

where

$\overline{C^t}$ = the time average oxygen content
$\mathcal{F}$ = constant rate at which the syringe is filled
C = instantaneous oxygen content
t = interval of observation.

The volume average concentration is equal to the quantity of oxygen in the beaker divided by the volume of blood in the beaker. Or expressed as an equation:

$$\overline{C^v} = \frac{\int^T F C dt}{\int^T F dt}$$

where

$\overline{C^v}$ = volume average concentration
F = instantaneous rate of flow from the artery.

An exact expression can be obtained for the difference between these two average concentrations. Let the flow, at any instant, be represented as the sum of the average flow over the entire interval of observation, plus the instantaneous deviation from the average. Likewise, let the oxygen concentration at any instant be similarly represented as the sum of the average (this will be the time average), and the instantaneous deviation from the average. Thus:

$$F = \overline{F} + \delta F$$

$$C = \overline{C^t} + \delta C$$

By substituting these expressions for flow and concentration in the formulas for the time and volume average concentrations, the difference between these two quantities, $\triangle C$ is obtained.

$$\triangle C = \overline{C^t} - \overline{C^v} = -\frac{1}{\overline{F}T}\int^{T} \delta C \cdot \delta F dt.$$

This formula is quite general and it is applicable to any specific situation involving a discrepancy between time and volume average concentrations. Unfortunately, from a practical point of view, this result indicates that detailed knowledge regarding the flow and the concentration of the reference material is needed in order to estimate the magnitude of the error incurred by using time average rather than volume average concentrations.

In order to illustrate the meaning of this expression, a calculation has been made for a hypothetical case of sinusoidal variations of the same frequency in concentration and flow. Figure 4 shows by means of a graph the assumed patterns of flow and concentration. The abscissa is proportional to time, the ordinate scale at the left gives the instantaneous flow corresponding to the upper line, while the ordinate scale at the right represents the instantaneous value of the concentration. The amplitudes are designated A and B and the phase angle by which the concentration wave leads the flow wave is given as α. For this case:

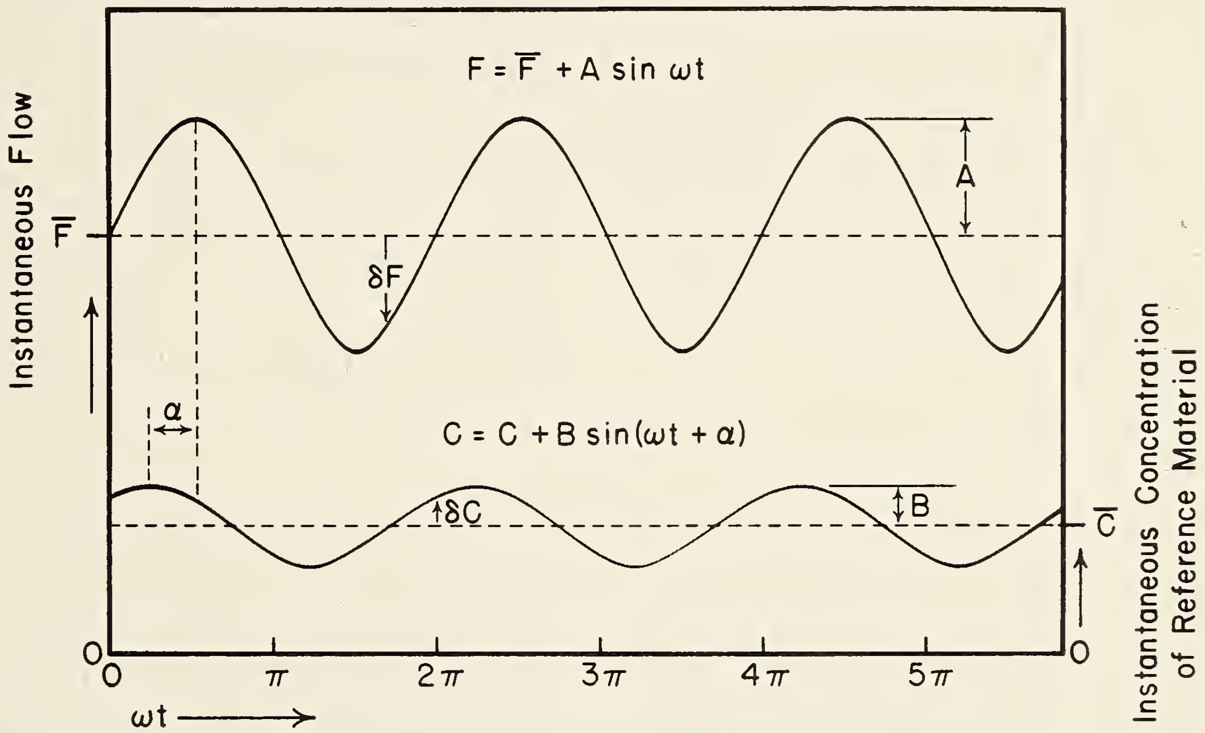

Fig. 4. Assumed sinusoidal variations in flow and concentration.

$$\triangle C = -\frac{AB\cos\alpha}{2\overline{F}}.$$

Since the discrepancy between the time and volume average concentrations is proportional to the cosine of α, it is evident that the time average concentration may be larger, smaller or the same as the volume average concentration depending on the value of α.

A general expression can be obtained for the fractional error in the calculated flow or output by considering the error due to the use of time average concentrations for both arterial and venous blood. The correct formula for average flow is:

$$\overline{F} = \frac{M}{T(\overline{C_o^v} - \overline{C_i^v})}.$$

The incorrect formula utilizing time average concentrations is:

$$\overline{F}^{*} = \frac{M}{T(\overline{C}_o^{\,t} - \overline{C}_i^{\,t})}.$$

The fractional error in flow is obtained by combining these expressions with $\triangle C$ as defined above.

$$\frac{\overline{F}^{*} - \overline{F}}{\overline{F}} = \frac{\int^{T} (\delta F_o \cdot \delta C_o - \delta F_i \cdot \delta C_i)\, dt}{M + \int^{T} (\delta F_o \cdot \delta C_o - \delta F_i \cdot \delta C_i)\, dt}$$

Only the sampling error has been considered in arriving at this result. The last formula cannot of course be applied in practice. However, it may serve as a guidepost in estimating the limiting error of this type when some of the details of flow and concentration at the sampling sites are known.

Within the framework of these formal conclusions, it is of interest to examine some of the factors which may produce fluctuations in flow and concentration and some of those which tend to smooth out or otherwise annul the effects of the variations. Although insufficient data are available to assess the importance of the various factors, it is perhaps justified to speculate briefly concerning them.

Arborization is one of the cardinal features of the vascular system. Both a branching in the arterial tree, and a confluence in the venous system, are possible sources of difficulty as related to the subject of the sampling error. First, consider a confluence in the venous system. If the oxygen contents of the blood flowing in the tributary vessels are different, any variations in the relative contributions of the small veins to the flow in the main vessel will produce fluctuations in the oxygen content of blood flowing in the larger vessel. Thus it is possible that such a site is the origin of concentration differences in the venous circulation. This situation is apt to occur in the case of the vena cavae and coronary veins supplying blood to the right atrium.

At a bifurcation in the arterial tree, the same process in reverse may be operative. If concentration waves are present in the parent artery, any time variation in the relative flow into the daughter vessels would result in differences in the average saturations of the blood flowing in the two smaller arteries. In this way, it is seen that a sample withdrawn from a peripheral artery might not be equivalent to one obtained from the main arterial stream.

In addition to this effect, systemic arterial blood may be subjected to variations in oxygen content in the process of becoming arterialized in the pulmonary capillaries. Information is lacking regarding fluctuations of the frequency of the heart rate, but in earpiece oximetry, undulations in oxygen saturation of respiratory frequency are sometimes observed even in normal subjects at rest breathing air. This finding is substantiated in the theory of respiratory gas exchange which indicates that substantial variations of this frequency may occur in arterial gas contents.[1,6]

Turning now to the question of the inconstancy of flow, recently, careful dynamic flow measurements made in animals have been reported. For example, McDonald[5] presents data obtained by high speed cinematography of the flow pattern in the abdominal aorta of the rabbit. He made simultaneous measurements of the velocity and pressure just distal to the origin of the renal arteries. His data clearly show that at the site of observation the pressure and velocity waves differ both in phase and form. Thus, in general the sampling error could not be avoided by merely allowing the variable pressure head to deliver the sample. Elimination of the error would require collection at a rate always proportional to the flow at the sampling site.

Thus far only those factors have been considered which emphasize the sampling error. There are, however, several ways in which the causes for error are dissipated. As the blood moves away from the source of time variations in composition, it travels with different velocities in the various lamina. The more peripherally the blood moves, the less pronounced the inequalities in composition become due to longitudinal mixing. Also, for instance, in the case of systemic arterial fluctuations in oxygen content, the differences in the path length from various pulmonary capillaries to the sampling site, tend to randomize the initial inhomogeniety.

A final point is worthy of mention. Previously attention was drawn to the importance of the separation in phase between undulations in flow and concentration in determining the magnitude and direction of the sampling error. This difference in phase is principally determined by two factors: (1) the velocity with which the flow and concentration waves travel (the concentration wave moves with the mean blood velocity while the flow wave moves considerably faster at approximately pulse wave velocity); (2) if the basic causes for the existence of these waves were of constant frequency, then the phase angle between the two would be constant at any particular site. However, the periods of physiological oscillations including the heart beat and the respiratory excursion are never precisely constant. Thus the phase angle even at one site would vary. This factor would also aid in randomizing the sampling error and hence in reducing its over-all effect.

Unfortunately, the status of this subject at present is decidedly uncertain. Whether there is appreciable error in the usual applications of the Fick principle is a matter of conjecture. Obviously, there are possible causes for error. An answer to the questions that can be raised may come from either of two directions. It would be helpful to compare the results of Fick measurements with a reliable direct method of determining blood flow at various levels of activity and with different inspired gas mixtures. Direct assessment of the significance of the sampling error can only be made on the basis of simultaneous dynamic measurements of flow and oxygen content at various places in the vascular system.

CONGENITAL CARDIAC DEFECTS—REFERRALS AND RECOMMENDATIONS

The general practitioner will not see many cases of congenital heart defect in his practice. When he does see one he is confronted with these questions: Is the murmur indicative of a serious defect? Is this an operable condition? Should the patient be referred for consultation? What shall the parents be told? How much activity should the child be permitted?

Any cyanotic type of heart lesion is serious, but only certain types may be operated on at present with the expectation of good clinical results.

In general, intense cyanosis, or an enlarged heart or an abnormally shaped heart on fluoroscopic examination is indicative of a serious congenital heart defect. These cases should be referred for consultation to a cardiologist familiar with hear disease in childhood, and the decision as to the necessity for special diagnostic procedures should be left to him. Parents should be told of the presence of a congenital cardiac defect, informed that it is not a disease, and a definite effort should be made to explain to them the nature of the defect, serious or otherwise. If informed by the family doctor whom they know and trust, the parents will be far less upset than if they learn of the defect through a routine school or club examination. The general practitioner is advised not to bring up the necessity for surgery before consultation unless he is sure of the exact diagnosis.

If the family physician plans to refer the child to a specialist, he has to be on his guard when he discusses his diagnosis with the parents or mentions the possibility of surgery to them. Because he wishes to persuade the parents to consult a specialist at once, he may be tempted to make a strong statement, but he will do much harm to the patient and the family if he tells them bluntly that the child has a heart condition and must have an operation or he will die. Cases of congenital heart defects are rare in his practice and the family physician often has no means of verifying the diagnostic impression gained from the history and the physical findings. There is always the chance that the diagnosis may be wrong and, even if it is correct, operation may not be indicated or may not be feasible.

Younger children with congenital heart defects rarely need to be limited in their daily activities by the physician or parents, as they will automatically limit themselves; this is especially true of children with cyanotic lesions. They need not be told to sit down and rest; the development of dyspnea will make them rest of their own accord. Older children with congenital heart defects, resulting in an enlargement of the heart, should not be permitted to take part in competitive sports, since their pride may force them to continue beyond their physical capacities.

Children with minor cardiac defects, such as a small ventricular septal defect, may be as active as they wish. Far greater harm will be done to the child if he is continually admonished to "be careful—go slowly" than if he is left on his own. These children do not need monthly physical check-ups except under special circumstances. School health slips should be carefully filled out, and emphasis laid on the degree of activity permitted; otherwise the teachers will tend to refuse to permit the child to join in any play.

If tooth extractions or operations such as tonsillectomy are indicated, they need not be avoided. Anesthetics may be administered safely to these children. Prophylactic medication should be given before and after the surgical procedure to avoid subacute bacterial endocarditis to which these children are especially susceptible.

The child with a congenital cardiac defect has been handicapped by nature. Every effort should be made to avoid creating an additional handicap by unnecessary restrictions. He should be allowed to live as active a life as possible.—From "Diagnosis of Congenital Cardiac Defects in General Practice," American Heart Association.

THE PHYSIOLOGY OF CONGESTIVE FAILURE OF THE CIRCULATION

W. F. HAMILTON, Ph.D.
Augusta, Georgia

I AM GREATLY HONORED to be asked to come to the University of Minnesota to deliver a talk on the Physiology of the Circulation. It is like carrying coals to Newcastle because work in this field has been very important in both the Rochester and the Minneapolis branches of the University.

I am particularly pleased that this lecture is dedicated to Dr. Fahr. For many years it has been my pleasure to look for him in the Federation meetings, to greet him as a friend, and then proceed to reap the riches of this great mind. I salute him as a great teacher, one who delights to share his very sound ideas and is ever patient and helpful to his younger associates.

My topic, the Physiology of Congestive Failure of the Circulation, is one about which there is much debate at the present time. Particularly is this true about edema. Our textbooks would have it that a high venous pressure will *ipso facto* result in edema by raising capillary pressure and augmenting filtration of fluid from the vascular system into tissue spaces. This oversimplified idea is attributed to Starling—though, in his original description of "Physiological Factors in the Causation of Dropsy,"[28] he stresses the unbalance between ingested water in excess of that excreted by the kidney. This produces hydremic plethora, which increases venous and capillary pressure. The resulting excessive transudation, according to Starling, leads to dropsy.

Since edema is constituted of large quantities of interstitial saline solution, we must agree with Starling that its accumulation of necessity results from intake of water and salt being greater than output. In heart disease it would seem that this unbalance is due to lessened renal output rather than to increased intake.[23]

Three ideas are ascendent as to the cause of renal retention of salt and water: (1) pre-renal deviation, (2) alteration of renal hemodynamics, and (3) hormonal disturbances. It may be that the adrenal gland or the pituitary gland secretes the key hormone.

In thinking of pre-renal deviation of salt and water, one meets the suggestion that the fluids are sequestered in the interstitial spaces so that they cannot get to the kidney. The cause is said to be high venous and capillary pressure resulting in transudation which not only causes the accumulation of dropsical fluids but also prevents their return to the bloodstream and kidney.

However, one does not need a high venous pressure in order to sequester fluids in the interstitial spaces. When one drinks a glass of water, or submits to an infusion, the fluid passes at once out into the interstitial spaces, and expands either the total body water (H_2O, D_2O) or the extracellular fluid (saline). It does this at a very rapid rate and with no measurable increase in venous pressure. Extra salt water is all that is needed to increase the extracellular fluid volume, and the reduction of this fluid volume is the simple result of getting rid of the salt water. This happens in heart disease by bed rest, digitalis, or diuretics in spite of a venous pressure persisting above normal levels. It happens in nephrosis spontaneously with the venous pressure normal during the accumulation and disposal of the dropsy.

The effect of increasing renal venous pressure upon sodium resorption is a temporary sodium retention when a ligature is placed around the cava just above the renals,[18] but this is permanent if the constriction is made above the liver,[5,27] indicating that renal venous pressure *per se* is not the key stimulus to edema formation. Temporary oliguria with sodium retention also results from exercise,[30] venous congestion of the extremities,[29] and pressure on the abdomen.[2] This last has been looked upon as illustrating the effect of increased venous pressure[2,26] but, since the kidney and vena cava are subject to the same ambient pressure, it is hard to see how the effective renal venous pressure can be increased by this maneuver. The ef-

---

The experimental work outlined in this paper is a co-operative venture of the Departments of Physiology and Thoracic Surgery of this school. Participating were R. G. Ellison, R. W. Pickering, E. E. Hague, and J. T. Rucker, Jr. It was made possible through grants from the U.S.P.H.S., and from the Life Insurance Medical Research Fund.

Presented in the Symposium on Recent Advances in Cardiovascular Physiology and Surgery, University of Minnesota, Minneapolis, September 14, 1953.

Dr. Hamilton is Professor of Physiology at the Medical College of Georgia.

fective arterial pressure, however, is lowered by the amount of the externally applied pressure as the arteries enter the abdomen.

Alternatively, retention of salt and water is said to be the necessary result of changes in renal hemodynamics. Thus, it is more difficult to get rid of sodium when there is lowered renal blood flow. Lowered blood flow lowers the filtration rate, ultimately, though the filtration fraction is increased. When the lowered filtrate formation displays sodium before the tubules in less amount than is their obligate reabsorptive function, a minimal amount of sodium is cleared from the body.[20]

As a general rule the glomerular filtration rate is reduced in congestive failure. However, in patients regaining compensation, sodium may be released with no consistent change in filtration rate. This is true whether the sodium load is high[3] or low[25]—whether filtration rate is measured by sodium thiosulfate,[3] inulin, or creatinine.[26] Tubular resorption of sodium (and water), through it is often more complete with low filtration, may be entirely independent of filtration.[3,7,12,13,25] This indicates that the resorptive mechanism is under direct physiological control and is not an obligate function of filtration rate. The fact that sodium excretion may be independent of filtration rate is further evidenced not only by the fact that subjects with low filtration rate will release sodium as they recompensate under the influence of bed rest, as well as after digitalization, and after the immediate influence of mercurial diuretics have passed off,[3] but also by the fact that circulatory handicap will lead to sodium retention even though filtration is normal.[5,13]

The evidence that the retention of salt and water is due to either prerenal deviation or to exclusively hemodynamic factors is not conclusive. Tubular function and the renal circulation seem, moreover, to be remote in their control from neurogenic factors—at least in the steady state.[30]

This leaves hormonal factors. The pituitary gland may play a key role. The posterior pituitary gland seems to be controlled by osmoreceptors[30] in its liberation of antidiuretic hormone promoting tubular resorption of water. Sight should not be lost of a possible mechanism involving the liberation of adrenocorticotrophic hormone to control the resorption of salt.

Conclusive evidence that the posterior lobe plays a role in the edema of circulatory failure is lacking. Presumptive evidence of its own activity is that the plasma sodium is often low in congestive failure and yet the patient suffers from chronic oliguria with antidiuretic substance in the plasma.[19] This would imply that some factor in heart disease stimulates the hypothalamo-pituitary mechanism to conserve water in greater amount than that needed to preserve the isotonic state.

That the adrenal does play a rôle is suggested by the fact that, when desoxycorticosterone acetate is given in excessive amounts to Addisonians, there result all of the signs of congestive failure of the circulation.[4] Remission of these signs occurs as soon as the drug is withdrawn.

It has also been shown by Davis and Howell,[5] that chronic passive congestion of the abdominal viscera, produced by partial obstruction of the thoracic inferior vena cava, caused retention of sodium and water. Upon adrenalectomy,[6] and the administration of cortisone, there was a prompt loss of sodium and water. Addition of desoxycorticosterone acetate in larger amounts than for ordinary maintenance, caused retention at a rate similar to that shown before adrenalectomy.

From the foregoing it would seem that a circulatory handicap may result in retention of salt and water with the formation of edema, and that the function of the adrenal gland, and possibly the pituitary, are important factors in this response.

In the hope of gaining insight into the physiology of the ascites of mitral stenosis, experiments outlined below were made on dogs. It was found, in brief, that when the mitral valve was gradually narrowed to a size comparable with that seen in severe clinical mitral stenosis, the animal became oliguric, excreted small amounts of sodium, and developed ascites. This occurred with normal venous pressures and could be reversed by withholding sodium or removing the adrenals, or simply by loosening the ligature. We have been unsuccessful so far in getting an animal to become ascitic, even with extreme stenosis, while afflicted with diabetes insipidus.[11,15,16,21,22]

The surgical operations described below were carried out by Dr. R. G. Ellison, whose work was a keystone in the investigation. Indispensable also were the constructive ideas and careful, painstaking work of R. W. Pickering, E. E. Hague, and J. T. Rucker, who took major responsibilty in the cardiorenal studies detailed herein.

For a long time it has been known that the mitral valve can be constricted sufficiently to give evidence of stenosis (early literature[9]), but without any clinical deterioration of the animal. It was found by Haddy and colleagues[14] that in animals in this condition, even though the mitral valve was constricted enough to increase the pulmonary venous pressure, the cardiac output and clinical condition remained normal. It has been our experience,[9] confirmed by Haddy et al,[14] that if an acute constriction of the mitral valve was produced, so that its aperture was of the order of 1 cm²/m², the animal died promptly of pulmonary edema.

We were interested in the occurrence of congestive failure after mitral stenosis. It seemed possible that the signs of this condition might appear if (1) the valve was not constricted at the time the animal was faced with the added handicap of deep anesthesia and post surgical shock, and (2) if the valve were constricted gradually and in such a manner that the constriction could be loosened when the signs of pulmonary edema appeared.

Operations

In order to do this, an operation was devised which is described elsewhere[9,10,11,15,16,21,22] and may be briefly outlined here. A special ligature was prepared, consisting of 28G stainless steel wire encased in 18G nylon tubing. Two 18G sharp needle tubes were pushed snug against the nylon tube and crimped in place on the wire.

The dogs were anesthetized under 10 mg/Kg. morphine and 20 mg/Kg. pentobarbital. The chest was opened aseptically by a rib spreading incision in the fifth interspace. The pericardium was opened and the ligature was threaded through the right auricle as near the septum and the floor as possible. (Fig. 1). It was drawn around the mitral ring and held in place by passing it under the epicardium in two or three places. The ends of the ligature were then drawn through a telescoping adjustable silver tube, one end of which was placed against the heart to hold this organ in place, and the other end between the fifth and sixth ribs and under the skin. The ligature was drawn snugly about the valve ring. The needles were cut away and a silver clip was bent around the ligature ends to hold them in place. The incisions were all closed with the usual surgical precautions.

When all wounds had healed and the animal seemed in good shape, the skin over the end of the tube was anesthetized, or light general anesthesia given, and the ligature ends exposed. They were then drawn tight enough so that a persistent (two or three minutes) weakening of the femoral pulse occurred. The ligature ends were re-clipped in the new location. This tightening was repeated at weekly intervals. The narrowing was 2 or 3 mm. above the mitral ring and left the leaflets functional. The mitral orifice was reduced in size comparably to that seen in severe clinical mitral stenosis (Fig. 2) and showed a murmur typical of the clinical disease (Fig. 3). The table indicates the pertinent facts relating size of the stenosis with the condition of the animal. The conclusion seems fair that when the mitral aperture is narrowed gradually it may be reduced to a very small size without producing acute pulmonary edema, whereas, as seen above, when it is constricted at the time of the operation, pulmonary edema and prompt exitus result even though the mitral orifice is

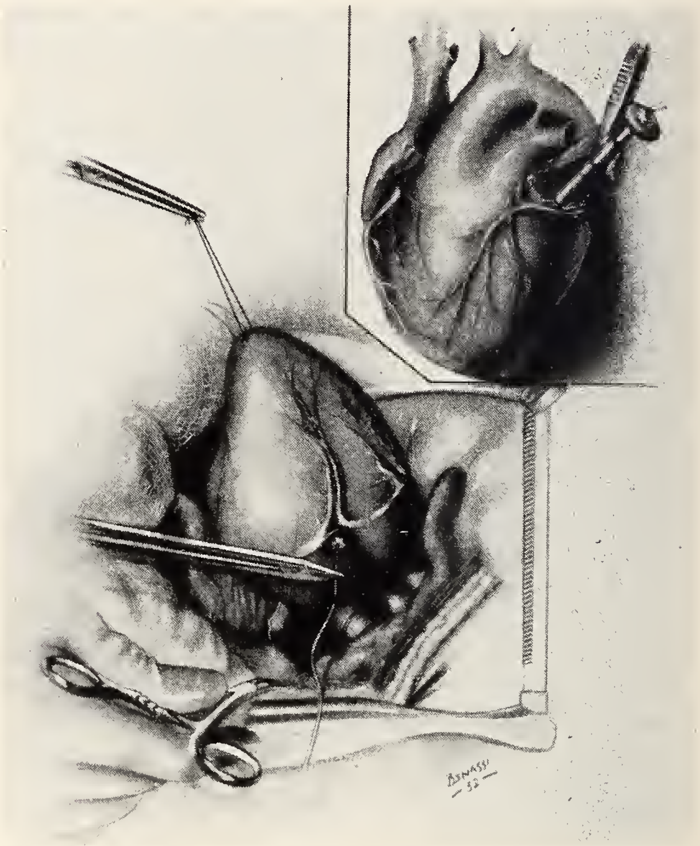

Fig. 1. Exposure of heart and placement of stenosing ligature (See text). Reprinted from Surgical Form.[10]

relatively large. The animals whose valves were gradually constricted developed a chronic state resembling, in some aspects, congestive failure of the circulation. After each tightening, there was an evanescent sodium retention and occasionally the temporary presence of ascites could be demonstrated. After a variable number of tightenings, urinary sodium excretion diminished to very low levels, and ascites accumulated prodigiously at a rate of sometimes 1.4 liters per week (Fig. 4). The ascites could be relieved by regular paracentesis or its formation prevented by administration of ion exchange resins and the animals kept alive from three to thirteen months.

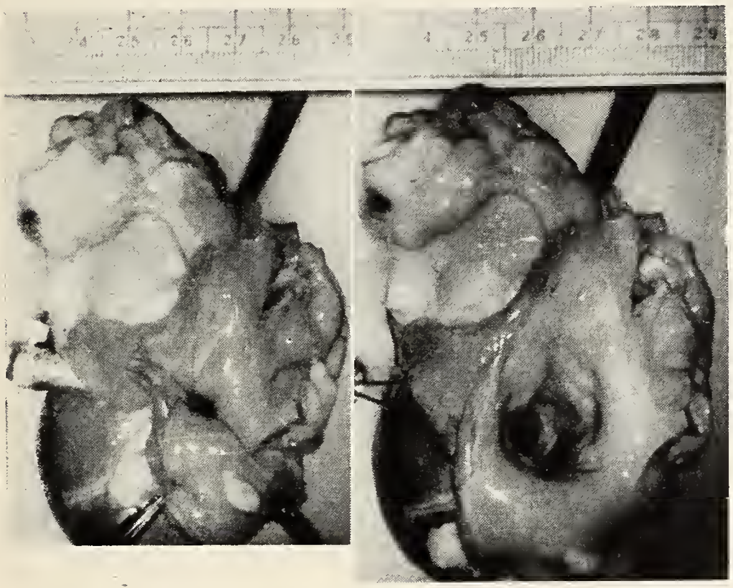

Fig. 2. The mitral orifice in mitral stenosis of controlled degree (right) as compared with a normal orifice. Reprinted from Surgical Form[10].

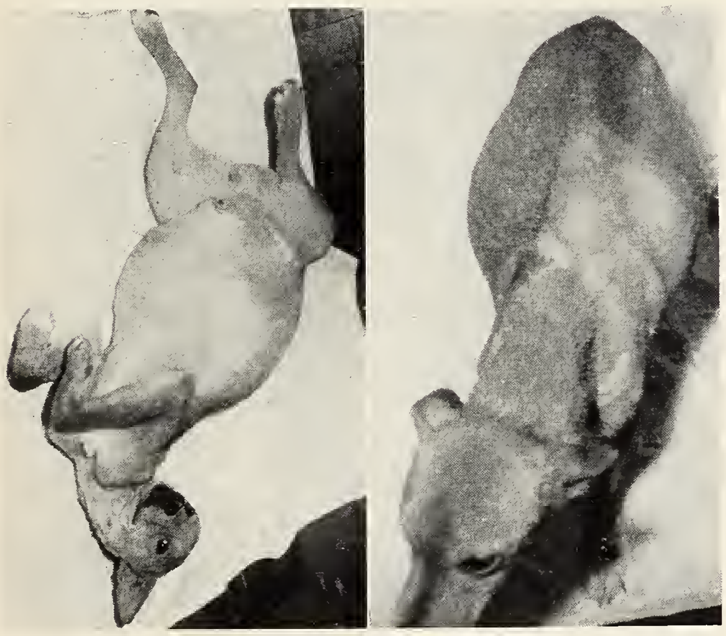

Fig. 4. Ascitic dogs with experimental mitral stenosis.

Except for those that were sacrificed, nearly all of the dogs died of terminal pulmonary edema. In two cases, a clot was found at autopsy causing an obstruction of mitral orifice further than that indicated by its anatomical measurement. The others may have had such a clot which was lost at autopsy. Another fact may explain the pulmonary edema. During the chronic course of the experiment, the plasma proteins gradually fell to low levels. This, by reducing the coloidal osmotic pressure, may have rendered the animals vulnerable to pulmonary edema at pulmonary vascular pressures not ordinarily dangerous.

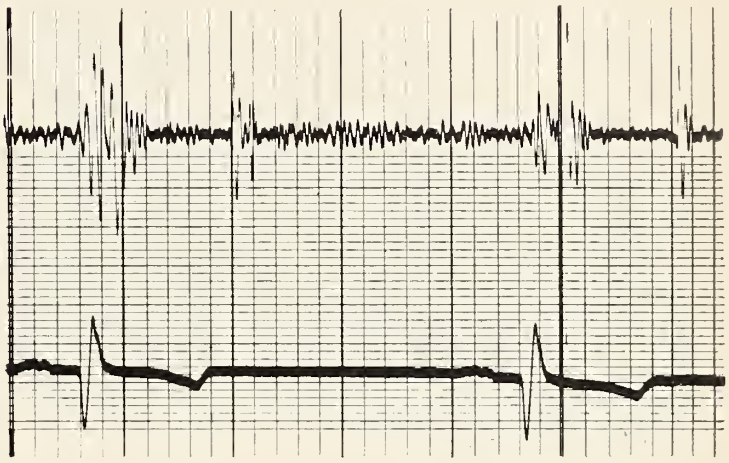

Fig. 3. Murmur typical of mitral stenosis from experimental dog, with simultaneous electrocardiogram.

Attention should also be called to the dog (H-9) whose pituitary stalk had been cut with probable injury to the hypothalamus. This animal had severe diabetes insipidus. It received a protracted series of seven tightenings, reducing the mitral orifice to a figure well below that associated with ascites in most of the other dogs. It may be that ascites is incompatible with diabetes insipidus.

The most obvious suggestion as to the cause of the ascites is that it results from simple filtration caused by a high venous (capillary) pressure. The venous pressure at the portals of the heart and the end-diastolic (filling) pressure in the right ventricle were not, however, above normal limits (Table I).

Not only was the central venous pressure normal, but there were none of the classical signs of chronic passive congestion. The spleen, kidney and liver were of normal appearance and size, grossly. The only microscopic abnormality was an obscure spotty hyperemia of the hepatic sinusoids and a complex convolution of the paralob-

ular venous channels. This affected only a few among many quite normal lobules. When ascites is produced by clamping the thoracic inferior vena cava and raising the abdominal venous pressure, the abdominal organs show clear signs of chronic passive congestion.[31]

On the other hand, when the dog was in the supine position the femoral venous pressure was definitely elevated. Nevertheless, edema of the feet and legs was not conspicuous.

The elevated femoral venous pressure is hard to explain except as the result of an increased pressure in the abdominal vena cava. The likelihood of this is enhanced by the fact that the superficial network of veins in the abdominal wall were greatly dilated, serving no doubt as a collateral drainage of the hind quarters.

To measure the pressure in the abdominal vena cava, a Cournand catheter was passed via the jugular vein, beyond the diaphragm, and the pressure was recorded. The abdominal caval pressure responded to manual pressure against the abdomen and, with the animal in supine position, varied from 12 to 14 cm. H_2O above the level of the catheter tip in the vena cava.

Now when the catheter was drawn into the thoracic part of the vena cava, the pressure fell to the normal venous pressure value (the height of the apex beat) or 6 cm. above the vena cava. There was a fall in pressure between that in the abdominal and thoracic inferior vena cava. It was caused, no doubt, by the fact that the contents of the distended abdominal cavity transmitted a pressure nearly equal to that in the vena cava, collapsing its walls about the contained blood, and contributing largely to the pressure measured in the great vein. As the blood approached the diaphragm the down stream pressure was reduced, the velocity increased, and the loss of lateral pressure (Bernoulli effect) caused further collapse of the vein around a fast jet of blood entering the inferior thoracic vena cava which was not subject to high outside pressure. Back pressure from this jet is responsible for the fact that pressure throughout the abdominal vena cava is slightly above that in the abdomen.[8,17] In the thoracic vena cava, blood pressure is not subject to conspicuous changes from abdominal manipulation as is the case in the abdominal vena cava.

The same experiment was performed on another dog whose belly was very tense. The pressure in the abdomen was 13 to 16 cm. H_2O of which 10 cm. could be accounted for by hydrostatic factors. The abdominal vena cava and abdominal pressures responded similarly to abdominal manipulation. The vena cava pressure (13 to 17 cm.) was not greatly different from that in the abdominal cavity, allowing for the hydrostatic weight of the abdominal contents. The difference between the thoracic and abdominal caval pressures was greater than in the first animal persisting in the natural position. Thoracic inferior vena cava pressure responded less than abdominal to pressure against the abdominal wall.

In whatever position, the caval pressure became nearly equal to that in the auricle as soon as the catheter tip passed the diaphragm, indicating that the ligature in no way interfered with the return of blood along the inferior vena cava, and that the high inferior vena cava and femoral pressures were due to the outside pressure from the abdominal contents.

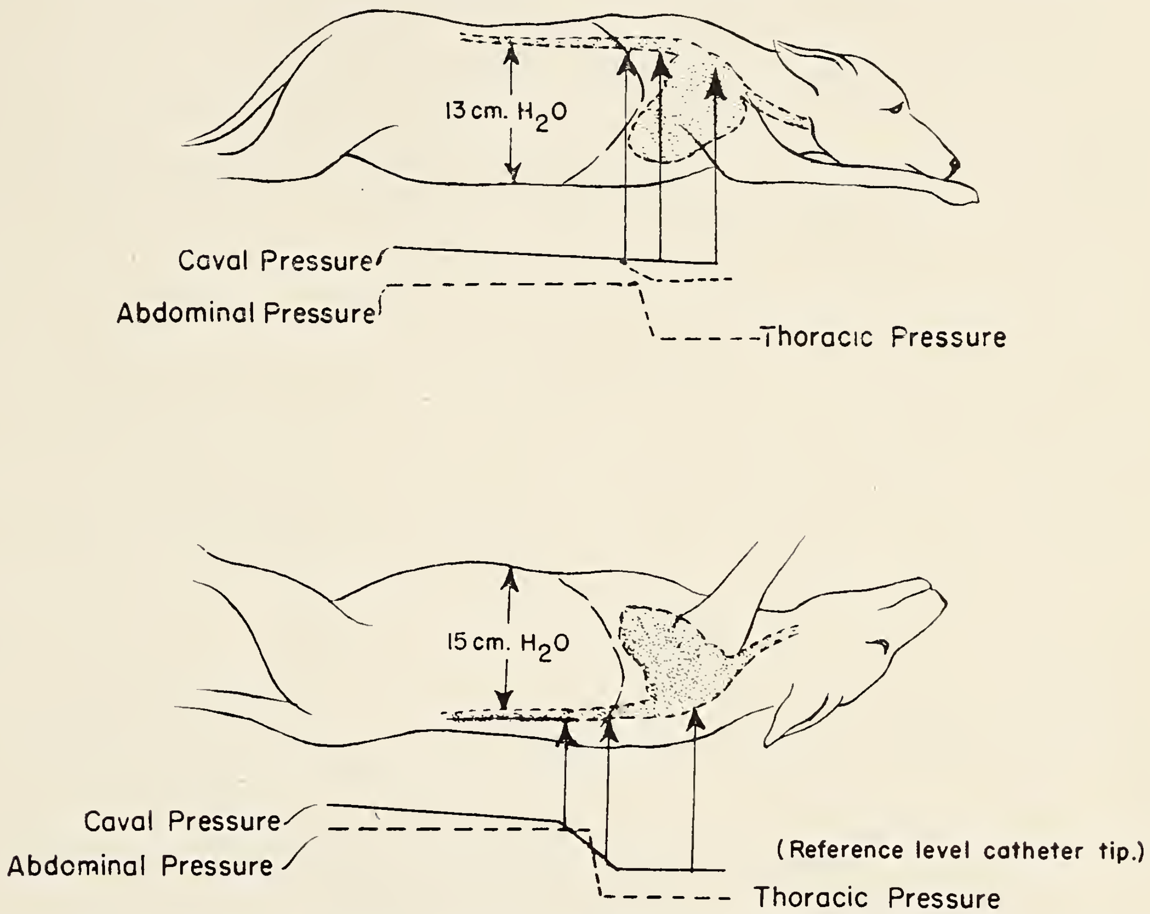

Fig. 5. Diagramatic representation of the fact that, though the pressure in the vena cava is high in ascitic dogs, it does not exceed by more than a few cm. H_2O the pressure in the abdominal cavity and, hence, cannot be responsible for the formation of ascites by simple filtration. Above animal in natural position; below, in prone position.

The table illustrates other hemodynamic findings. Although the cardiac filling pressure is low, the pulmonary vascular pressures are somewhat elevated. The cardiac output is at, or slightly below, the low normal level (pentobarbital anesthesia). It is hard to see anything in the hemodynamic picture to cause the ascites. The fact that the arteriovenous oxygen difference is wide, and the mixed venous O_2 tension low, may play a rôle.[3]

Without venturing an hypothesis as to how the direct effects of the ligature produce it, we have evidence that there are changes in renal function which occur with the development of ascites.

The renal blood flow and filtration rates were measured by the clearance of paraaminohippuric acid and of endogenous creatinine. The dogs were trained to lie quietly on the table while samples were being taken. As will be seen from the table, both of these measurements tended to be low in dogs with ascites, but rarely did they fall below the lowest measurements seen in normal control. The kidney seems to have handled blood and filtrate in an essentially normal manner. The reabsorption of sodium (and water) seem to be the renal functions which are most greatly changed. The renal tubule, in response to an unknown mechanism, has been stimulated to reabsorb sodium (and water) from the glomerular filtrate almost completely. Water and sodium seem to have been handled by the kidney in a coordinated manner because, whether the animal was gaining his ascitic pool or losing it, the plasma sodium remained within normal limits. Only the adrenalectomized animal had a low plasma sodium.

The chronically ascitic animal can be made to lose his pool of ascitic fluid. Attempts to cause this by the administration of digitalis or of mercurical diuretics were of no avail. The diversion of dietary sodium into the feces by means of ion exchange resins (carbo-resin, Lilly) often resulted in a dramatic drying out of the animal. The protocol in Figure 6 illustrates some of the things that happened in our experience.

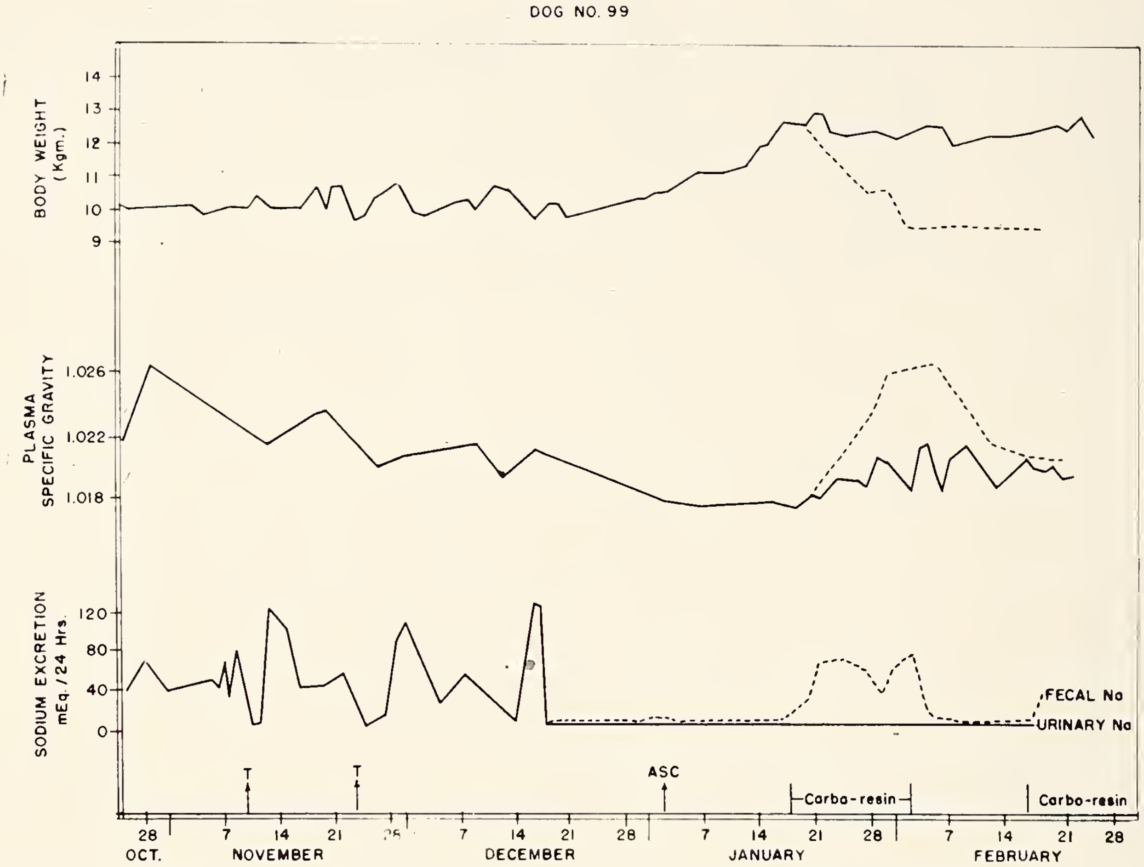

Fig. 6. The course of body weight, plasma specific gravity and sodium excretion in response to the administration of carbo-resin (Lilly). The dog indicated by the solid line was followed through the whole experiment. The dog indicated by the dotted line responded better to the resin (See text).

When the ligature was first tightened, the animal retained sodium for a day or so and then excreted it in excess. A second tightening resulted in the same response, followed by erratic urinary levels which finally eventuated in almost complete sodium retention and the formation of ascites. The body weight increased, the plasma protein level decreased, and the abdomen swelled conspicuously. As carbo-resin was administered, the sodium output (fecal) came into balance with the intake, the body weight leveled off, and the plasma protein returned to normal levels. Another dog whose response to carbo-resin was better (broken line), lost weight on the exhibition of the ion exchange resin, her ascitic pool was evacuated and her plasma proteins, after an overshoot, returned to normal values, which persisted as long as the resin was administered. Withdrawal of the resin caused this animal to become ascitic with low plasma protein levels. Animals can be induced to go through this cycle several times.

A similar cycle occurred when two dogs frayed their ligatures in two, releasing the mitral stricture. The sodium balance was restored by urinary excretion of sodium rather than fecal loss. The clinical picture was similar in that both animals lost their ascitic fluid and had an episode of concentrated plasma protein, which soon returned to normal. The animals became in all respects normal except for the hardware in their chests.

A very curious event occurred in the case of three dogs. In two animals, after two or three tightenings, no effect on the femoral pulse resulted from further tightening. On a later attempt the ligature came out in our hand. We were amazed to find it unbroken. It had evidently sawed its way through the auricle, much as a weighted string pulls through a piece of ice. The heart healed behind the ligature as it worked through the auricular walls and septum. The animal became quite normal and showed no signs of discomfort. In the case of the third animal the unbroken ligature was found free of the heart at autopsy.

The ascites began to form when plasma protein and venous pressure were within normal limits. Moreover, when carbo-resin was displayed, or when the ligature broke, the animals had an ascitic fluid whose protein concentration (normal AG ratio) was only 1 to 1.5 per cent lower than that in the plasma. The relation between hydrostatic and osmotic pressure was such as might be expected to lead to filtration. Nevertheless, the ascitic fluid was promptly evacuated as soon as the effective sodium intake was lowered or, in the broken string animals, as soon as the hemodynamic picture was made more nearly normal. This would seem to be brought about by a lessening of the stimulus (whatever it is) which causes the tubule to resorb water and sodium.

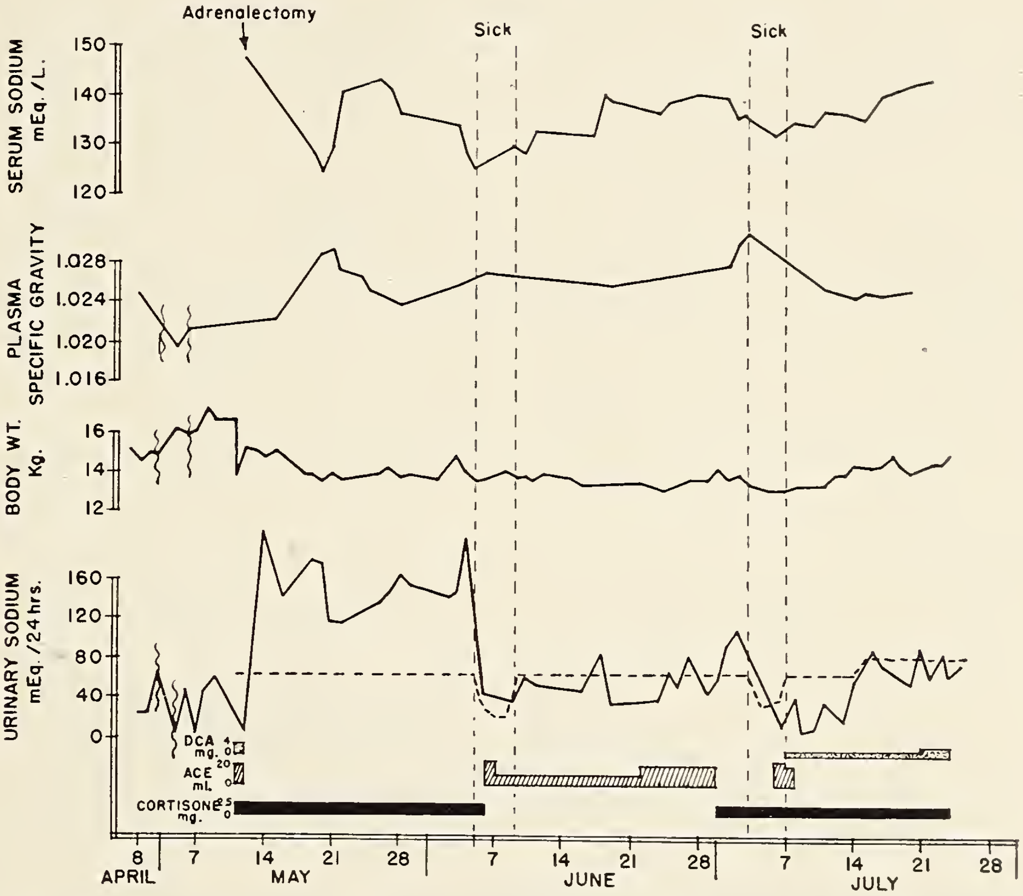

Fig. 7. Effect of adrenalectomy and substitution therapy in dogs with ascites from experimental mitral stenosis. (For details, see text.)

The immediate cause of the change in tubular resorption is probably hormonal. The amorphous part of the adrenal secretion is usually regarded as controlling the resorption of salt, and the posterior lobe hypothalamic mechanism probably controls the resorption of water. Neither salt nor water can be resorbed alone, but excess of adrenal hormone may cause the resorption of sodium followed by water, and excess of the pituitary hormone may cause resorption of water followed by salt. The pituitary mechanism has been implicated when plasma sodium levels, in congestive failure patients, are low and the plasma antidiuretic titer high.[19] The adrenal mechanism has been implicated by experiments that show that disoxycorticosterone acetate will produce edema, pulmonary congestion, and enlarged heart, making up the syndrome of congestive failure.[4]

Our dogs with mitral stenosis had normal sodium levels in their plasma. It was therefore decided to test both the pituitary mechanism and the adrenal mechanism.

After several attempts to get diabetes insipidus with hypothalamic injury and stalk section, by means of an operative approach with direct vision and by means of a stereotaxic instrument, two dogs, one of which died before the experiment was complete, were prepared with clinical evidence of the disease. On the surviving dog, the ligature, previously placed around the mitral valve, was tightened seven times at intervals of a week or more. She finally succumbed to pulmonary edema. At autopsy the mitral aperture was only 8 sq. mm. (19 mm^2/m^2), a size much smaller than those found in most of our other ascitic dogs. During nine weeks the tightening was repeated to produce sustained weakening of the femoral pulse, and no retention of sodium or formation of ascites occurred. Less than four such tightenings always produced ascites in our normal animals. We are left with the hypothesis that diabetes insipidus protects against sodium retention and ascites formation. During the last three days of the animal's life, urinary sodium was low but the belly was dry post mortem.

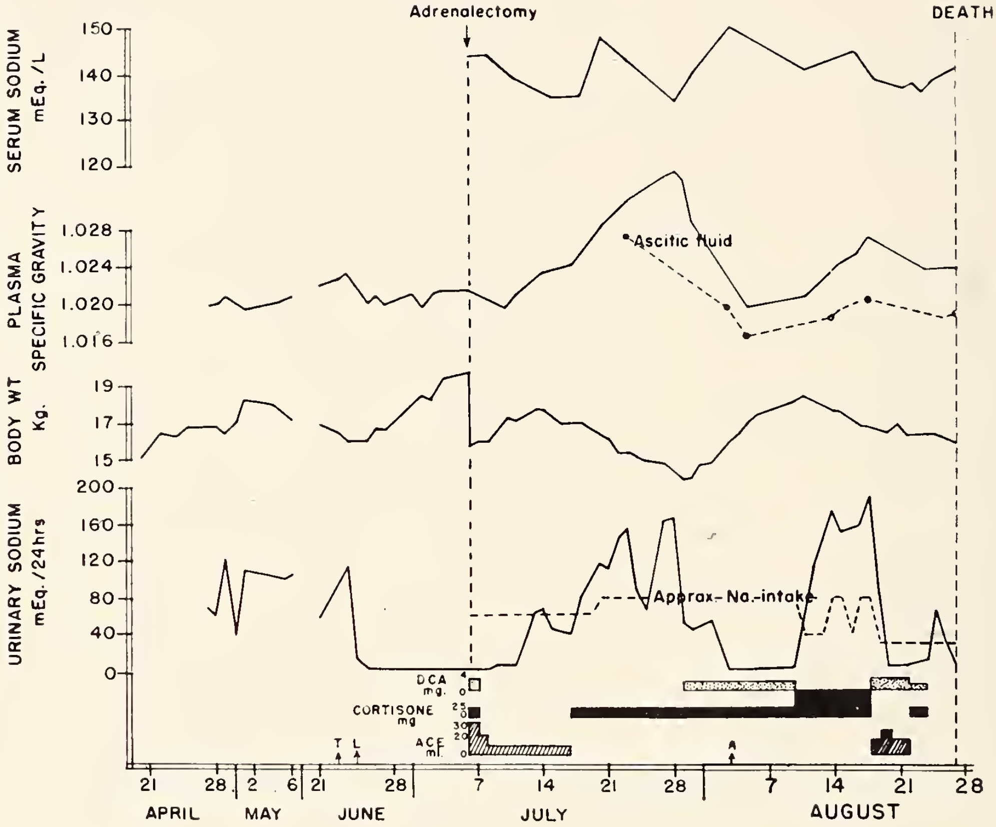

Fig. 8. Effect of adrenalectomy and substitution therapy in dogs with ascites from experimental mitral stenosis. (For details, see text.)

An attempt to produce diabetes insipidus in a dog already ascitic failed because of cellulitis and edema at the site of the operation.

To test the rôle of the adrenal gland, three animals were adrenalectomized on one side, the ligature placed and tightened until ascites appeared. One animal died. The other two became ascitic, and the second adrenal was removed. The first animal (Fig. 7) was treated for two postoperative days with whole adrenal extract, 25 cc. per day. When she was in good shape, extract was withdrawn and cortisone, 25 mg. per day was administered. What ascitic fluid had not been spilled during the operation was promptly evacuated and urinary sodium was markedly increased. The specific gravity of the plasma overshot, and then returned to normal. The animal was very vigorous. As soon as the ascitic fluid was gone, the plasma sodium decreased, the animal lost her appetite and showed other signs of adrenal deficiency. The cortisone was discontinued and she was given 10 cc. per day of whole adrenal extract (Upjohn). She came promptly into sodium balance and good health. Twenty cc. per day—four times the dose for normal adrenalectomized animals—did not cause any salt retention. Under the stimulus of mitral stenosis, the adrenal gland must have secreted an amount of the salt retaining hormone in excess of that contained in four maintenance doses of extract.

Cortisone treatment was then repeated. The animal again showed low plasma sodium levels and became ill. She was restored to vigor with a few doses of whole extract and maintained at that level with cortisone, 25 mg. per day and desoxycorticosterone acetate, 2 mg. per day. At autopsy the ligature was broken.

The second animal was adrenalectomized while in failure (Fig. 8). She was given 10 cc. per day of adrenal extract while she was still ascitic and came into approximate sodium balance without loss of ascites. Substitution of cortisone caused her to lose sodium and ascites in a profuse diuresis. The plasma sodium level remained normal and the animal vigorous as long as the store of ascitic fluid was available. When it was gone, the plasma sodium declined, and the animal became ill. Addition of desoxycorticosterone acetate, 2 mg. per day, put the plasma sodium back to normal and caused her to become vigorous again. The sodium excretion soon became minimal and the ascites returned. The desoxycorticosterone acetate was withheld, the cortisone dosage was increased to 75 mg. per day. The ascites was evacuated and the sodium excretion increased very much. The animal deteriorated at this point and died while we were attempting to improve the substitution therapy.

Conclusion

In concluding, it may be said that the mitral stenosis produced in these dogs resembles closely, in the size of the mitral orifice, and in the nature of the murmur, the condition seen in severe clinical cases. It leads to congestive failure (ascites) but this condition in the dog differs from congestive failure in man in that the fluid is collected in the abdomen rather than in the interstitial spaces. The effects of posture and gravity can be assigned a rôle in this difference.

The condition of our dogs lacks another of the usual signs of human congestive failure—*viz.* a high venous pressure. However, there are many clinical cases on record of cardiac edema with low venous pressure and many with high venous pressure and no edema.[1] Patients will gain or lose edema fluid regardless of whether their venous pressure is high or low if maneuvers are undertaken to correct renal errors in water balance.

The low venous pressure, and the absence of signs of passive congestion in the abdominal viscera, minimizes the rôle of possible forced filtration in these dogs. The amelioration of the ascites with sodium deviation by means of carbo-resin emphasizes the rôle of sodium in the disturbance. The fact that renal blood flow and glomerular filtration were not unduly restricted, indicates that the primary disturbance is a stimulation of the resorbtive function of the tubules.

The result of adrenalectomy implicates this gland and the fact that ascites would not increase under four times the maintenance dose of cortical extract implies either that the secretion of the gland was very excessive as a result of the stenosis, that the adrenal secretion was abnormal in character, having an undue amount of the salt retaining (amorphous) fraction or else that, in addition to the adrenal disturbances, there may be a disturbance in the function of the posterior pituitary.

Evidence that the pituitary is involved is very tenuous. It is only that the dog with experimental diabetes insipidus did not become ascitic under conditions that made other dogs ascitic. Further work is going on in an attempt to elucidate this problem.

It is interesting to speculate as to the rôle which this endocrine mechanism may play in health. Can it be decided whether we are working with a homeostatic mechanism that is being over stimulated, or an emergency response that is being continuously activated, either of which might lead to the vicious cycle seen here.

Gauer has presented evidence in this symposium that experimental procedures which tend to increase the effective local pressure of the blood within the great veins, right heart, and lungs, cause an increase in the output of salt and water. This is evidently a homeostatic mechanism. The stimulus, an increased distention of the low pressure blood reservoir, being the resultant, naturally, of an increase in the intravascular volume and the diuresis which eventuates, would decrease fluid and blood volume.

However, Gauer's mechanism is not the one that causes dogs with mitral stenosis to form ascites. Both the Gauer and the present procedure cause elevation of the effective pulmonary vascular, and right heart pressures. Gauer's dogs have diuresis; the mitral stenosis dogs have oliguria. It seems that we must think that the mitral stenosis dogs are making use of an emergency rather than a homeostatic mechanism. The oliguria of exercise,[30] which conserves salt and water, may be overstimulated and continuously activated until sodium practically disappears from the urine and ascites develops. The circulatory handicap may act like chronic exercise and set the mechanism off. The post pituitary is undoubtedly involved in the oliguria of exercise and may, perhaps, be over active here. An atypical stress reaction[24] may involve the adrenals. The picture is not clear and much further work should be done.

COARCTATION OF THE AORTA

Coarctation of the aorta will vary from a partial narrowing of a considerable portion of the aortic arch to a severe localized constriction. Mild cases of coarctation will be asymptomatic and may be discovered only at necropsy. The chief clinical finding is *evidence of hypertension in the upper extremities* with decreased to absent pressures in the lower extremities, as manifested by faint or absent femoral pulsations. (Normally the pressure in the leg is greater than that in the arm.) Murmurs may or may not be present. The classic x-ray finding of notching of the ribs is rarely found before the age of fourteen years, as it takes time for the collateral circulation to cause pressure erosion of the ribs. Operation is indicated if the hypertension is severe or increasing.

The optimum time for surgery is under fourteen years of age because of the early appearance of arteriosclerotic plaques in the aorta, with consequent technical difficulties in suturing after excision of the narrowed portion.—From "Diagnosis of Congenital Cardiac Defects in General Practice," American Heart Association.

LABORATORY DIAGNOSIS OF HEMOLYTIC DISEASE OF THE NEWBORN

DON R. MATHIESON, M.D.
Section of Clinical Pathology, Mayo Clinic and Mayo Foundation
Rochester, Minnesota

THE laboratory diagnosis of hemolytic disease of the newborn is usually based on the demonstration of four general requirements: (1) Rh incompatibility between mother and father; (2) maternal Rh antibodies for erythrocytes of the father's Rh type; (3) presence of maternal antibodies on the infant's erythrocytes and (4) objective evidence of increased destruction of the infant's erthrocytes.

Demonstration of Rh Incompatibility

Proof of Rh incompatibility between parents depends on the reliability of tests to determine the presence or absence of Rh factor in erythrocytes. In general, such tests are reliable. However, shortcomings in routine Rh testing do exist. Occasional batches of testing serum with low potency are obtained from manufacturers. Increased demand for serum and decreased production have caused dangerous shortage of supplies at times.

Errors in Rh testing sometimes are made because tests are performed too soon after transfusion of blood of unknown Rh type. Errors occur because abnormalities in the patient's serum proteins may affect the results. Such errors are less common in obstetric patients than in patients who have chronic and complicated illnesses, such as lupus erythematosus, leukemia or malignant tumors. The only obstetric patients in whom this error might arise are those recently recovered from primary atypical pneumonia who have autoagglutinins that might give false positive results in an Rh negative person.

Demonstration of Maternal Antibodies

When the Rh factor was first discovered, antibodies could be found in only about half of the patients who had babies with hemolytic disease. Later, with the discovery that Rh antibodies differed from other antibodies, it became possible to increase the sensitivity of these tests so that antibodies could be found in 98 per cent of mothers who later had affected infants. At present, tests for antibodies have fallen into some disrepute because workers developed overly sensitive tests and reported antibodies in many patients who had normal babies. Also, faith was lost in the tests because it was found that the titer of antibody did not have the prognostic significance originally claimed for it. For example, increasing titers during gestation were not invariably associated with severely affected infants.

Methods of testing for antibodies at the Mayo Clinic have not been changed during the past six years; these methods have given satisfactory correlation between the presence or absence of antibodies and the occurrence of disease in the infant. The sole object of such tests should be the prediction of disease in the infant so that all necessary arrangements can be made for proper management at birth. The ideal time to do these tests is as late in gestation as possible and yet in time to make arrangements for handling the problem at birth.

Demonstration of Maternal Antibodies on the Infant's Erythrocytes

Maternal antibodies on the infant's erythrocytes usually are detected by the antiglobulin, or Coombs', test. Experience with this test indicates that when antibodies are found consistently in the mother results of the Coombs test at birth fre-

This is the twelfth in a series of editorial reports sponsored by the Minnesota Society of Clinical Pathologists and designed to foster closer relationships between clinicians and pathologists.

quently are positive and other evidence of hemolytic disease is found. Negative results are obtained occasionally when other evidence of disease is present. Thus, positive results indicate trouble but negative results may be misleading. The Coombs' test should not be relied on as a sole means of diagnosis but should be performed along with other tests to meet the fourth laboratory requirement for diagnosis of hemolytic disease, namely evidence of destruction of the infant's erythrocytes at birth or within the first 24 hours of life.

Demonstration of Hemolysis

The best indicator of abnormal destruction of the infant's erythrocytes is an increase of indirect serum bilirubin to values of more than 4.5 mg. per 100 ml. of serum obtained from cord blood. The next best test is a decrease in erythrocytes to less than 3,500,000 per cubic millimeter of blood and next an increase in the incidence of reticulocytes to more than 10 per cent and of normoblasts to more than 15 per cent.

Therefore, the following laboratory tests are ordered and obtained immediately on babies born of Rh negative mothers who have Rh antibodies: serum bilirubin (cord blood), test for Rh factor, antiglobulin test and counts of erythrocytes, reticulocytes and normoblasts.

Comment

The diagnosis of hemolytic disease of the newborn is sometimes made although all four requirements are not met. The pathogenesis in these cases is not fully understood. Some investigators explain these cases on the basis of ABO rather than Rh incompatibility. Thus, one theory assumes that natural anti-B isohemagglutinins in the circulation of a group A mother may traverse the placenta and react with B substance on or in the infant's erythrocytes, leading to their abnormal destruction.

Death from hemolytic disease appears to be closely allied to toxic effects related to sudden breakdown of erythrocytes. Therefore, treatment now is being directed mainly at immediate replacement of the infant's blood with normal blood when any evidence of increased destruction is present. Thus, the presence of clinical jaundice within the first twenty-four hours, confirmed by values for indirect serum bilirubin of more than 4.5 mg., is a positive indication for replacement transfusion. Replacement transfusion using 500 ml. of blood usually causes about 50 per cent reduction in the value for serum bilirubin. It also eliminates from the infant's circulation any sensitized erythrocytes that have not yet been destroyed. If values for bilirubin continue to increase and go above 20 mg., further replacement transfusion is done.

Summary

The most important and vital need for successful management of hemolytic disease is the detection of jaundice during the first 24 hours of life. The explosive suddenness with which the hemolytic process sometimes develops without warning evidence emphasizes the fact that no substitute exists for almost constant observation of newborns for the appearance of jaundice, confirmed by measurement of serum bilirubin. The appearance of jaundice is an indication for immediate treatment.

LYON LABORATORIES DEDICATION

The new Elias P. Lyon Laboratories which include laboratories for cancer and heart research among others, will be dedicated February 11 in ceremonies to be conducted at the Coffman Memorial Union, University of Minnesota. Featured speakers at the dedication ceremonies will include President J. L. Morrill speaking for the University of Minnesota, representatives of the Public Health Service, and Dr. M. R. Runyon, executive vice president of the American Cancer Society.

The Minnesota Division, American Cancer Society, which supplied a major share of the funds for the construction of the new laboratory building, will conduct a workshop for state volunteer cancer workers in the Hotel Normandy, Minneapolis, February 10 and 11. Speakers who will help bring cancer information up to date for the field workers will include Dr. Bernard Zimmermann, cancer co-ordinator, University of Minnesota, and Dr. David Anderson, Austin, president of the Minnesota Division, American Cancer Society. Dr. John Bittner will conduct a tour of the University's cancer research facilities and Dr. Claude Hitchcock will be in charge of cancer exhibits in Coffman Union.

The Dean's Page

THE CANCER DETECTION CENTER

Intensive clinical and basic research during the past several decades has failed to provide a simple, direct, method of diagnosing cancer. At the present time many avenues of approach to this problem are being explored in various medical centers. While we wait and hope, it is imperative that we exhaust the possibilities of known methods for establishing a correct and early diagnosis of malignant disease.

It is becoming more apparent that earlier diagnosis and immediate treatment are the most significant procedures by which real improvement in long-term cancer patient survival will result. In order that this may come about for larger groups of people, increased emphasis must be directed to precancerous conditions and suspicious lesions. It is essential that all members of the medical profession join actively in this effort. In truth, "Every Doctor's Office Should Become a First Line of Defense as a Cancer Detection Center."

"Cancer detection" carries a unique significance as compared with "cancer diagnosis." Diagnosis implies the establishment of the cause of symptoms existing in a given patient. "Detection," on the other hand, indicates the finding of malignancies, pre-malignant conditions, or suspicious lesions or in symptom-free patients undergoing periodic check-ups.

The Cancer Detection Center at the University of Minnesota was established five years ago to test whether it would be feasible to examine large numbers of asymptomatic people for the earlier detection of malignancies in all organs of the body. Other Cancer Detection Centers have dealt primarily with organs readily accessible to the examining physician. This Center has placed emphasis on internal organs. It is now possible to review this five years' work.

During this five-year period, 5,352 patients were given a total of 11,343 examinations. A total of ninety cancers have been found. Precancerous lesions were present in 1,300 of the examinees.

In spite of our efforts to do so, it has been impossible to limit examinations at the Detection Center to individuals completely free of symptoms. We have divided, therefore, our cases of cancers into two groups: those with some symptoms referable to the organ or organ system in which cancer was found, and those who were without symptoms for the organ or organ system involved. On this basis, cancer has been diagnosed in forty-four patients with symptoms and in forty-six patients without symptoms.

An immediate point of interest was whether there has been a significant difference in the survival of patients who had lesions detected in the absence of symptoms as compared with those who had symptoms which, in all likelihood, would soon have taken them to their family physician. In the gastrointestinal tract, including the stomach, large bowel, and rectum, there were twenty-nine cancers diagnosed. Ten of the lesions were in persons with symptoms and nineteen were in persons free of symptoms of gastrointestinal disease. At the present time, there are only two survivors in the group with symptoms of gastrointestinal disease, while fifteen of the asymptomatic group of patients, are living and well. All of these patients received therapy through customary channels of medical practice throughout the state of Minnesota. It appears that the most significant factor in the difference of survival has been the early diagnosis of the lesions in the asymptomatic phase of the disease.

The Detection Center at the University Hospitals has used a routine, comprehensive type of complete examination composed of standard diagnostic practices. We have found achlorhydria or extreme hypochlorhydria to be an accurate aid in selecting patients who should have gastrointestinal x-ray examinations. The proctosigmoidoscopic examination of the rectum and sigmoid has been extremely

Justus Ohage, M.D.
President, Minnesota State Medical Association

President's Letter

NEW YEAR, NEW CENTURY

It is with great pleasure that I begin the year as president of the Minnesota State Medical Association. I am honored to have been chosen to represent the medical profession of Minnesota in the highest position its organization can confer on a doctor.

Traditionally, the office of president of the state medical association has carried with it the esteem of medical men in the state, the inherent dignity of any such position of leadership, and the dedication and selflessness of the men who have held the position in the past.

The men who have preceded me as president have exuded those qualities in great measure; they have been exemplary figures representing the purposes of medicine; they have deserved the trust placed in them by their colleagues; and they have been able leaders, strong and forthright in their beliefs.

With such an inspiring tradition, I pledge myself to carry on their noble ideals, for I have a deep respect for their work and for the profession's central purpose—to promote the science and art of medicine; to elevate the standard of medical education; and to promote public health.

Furthermore, 1954 marks the beginning of a new era for the Minnesota State Medical Association. With this year we are inaugurating a new century of medical organization in the state—having celebrated the centennial milestone last year.

Thus, I feel doubly proud to head this fine organization as it embarks on its second century of vigorous existence. What this new century will bring, none of us can tell. But one thing is certain: the underlying strength of the profession will increase its stature, broaden its outlook, and spur it on to even greater accomplishments.

During the coming year, I intend to work with the profession in Minnesota to bring that ideal one step closer. Working together with Association committees, the Council, the county medical societies, the House of Delegates and individual members, we shall make continued forward progress as an organization.

Thus, it is an honor and privilege for me to serve the medical profession of the state as its president. In spite of probable setbacks and pitfalls, with such a fine organization as ours, one cannot help but see that improvements will be forthcoming, and achievements will be more numerous.

J. Ohage.

President, Minnesota State Medical Association

◆ Editorial ◆

Arthur H. Wells, M.D., *Editor;* Henry G. Moehring, M.D., and John F. Briggs, M.D.

BOARD OF EDITORS

THE COUNCIL created a Board of Editors of MINNESOTA MEDICINE at its September session, and appointed ten members to the Board at the December meeting. This group is entrusted with the solicitation, selection, editing and publishing of scientific papers and news items of our journal. The organization and its functions appear in certain respects to be unique. Each member has specific and indispensable editorial duties.

Acting on the theory that one of the principal functions of the State Medical Association journal is to help develop self-expression and professional authority within the state, Dr. Glenn J. Mouritsen of Fergus Falls will seek out desirable scientific presentations in the county and regional medical society meetings throughout the state. A second Scientific Assembly Editor, Dr. Tague C. Chisholm of Minneapolis will cover meetings of state-wide medical organizations and those in the Twin Cities. Dr. L. E. Steiner of Albert Lea will edit a Business Assembly Section of the journal. Drs. Henry G. Moehring of Duluth, and John F. Briggs of Saint Paul will be responsible for the Editorial Section. Miss Olive V. Seibert, the publishers' editor, will represent a fundamental link with the Bruce Publishing Company. Dr. Alex E. Brown with Dr. George Stilwell, of Rochester, and Dr. Robert B. Howard with Dr. Stuart W. Arhelger, of Minneapolis, will represent the two great scientific fountains of our state. Among other things, they hope to develop a section of the journal which will compare with the popular brief reviews of several commercial magazines. Their slogan is "MINNESOTA MEDICINE, the Bedtime Companion of Every Physician."

Any alterations in the editorial organization or the published journal are not to be considered as criticisms of the past, but are based on the theory that a trial of variations in all of man's activities is essential to progress. Please keep in mind that the standing of a state medical journal is principally limited by the professional attainments and support of the membership.

CARDIAC SYMPOSIUM

THE scientific section of MINNESOTA MEDICINE in the January and February issues will be devoted to the presentations of the Symposium on Recent Advances in Cardiovascular Physiology and Surgery, held at the University of Minnesota on September 15, 1953. This meeting of outstanding authorities from the scientific centers of the world was made possible through the unusual efforts of Dr. Grace M. Roth, Dr. Robert B. Howard, Dr. John F. Briggs and many other physicians of our state and by the financial support of the Minnesota Heart Association.

You can keep up-to-date by reading MINNESOTA MEDICINE.

FORECASTS

THE first month of a year is the time for giving that year a prognosis. Some people call this forecasting and make it a favorite sport during January. From our friends, we have gleaned some general rules about these forecasts; to wit, (1) If you want to be spectacular, go ahead and make definite predictions about our economic future, the outcome of the next elections, or whatever you prefer to forecast about. But don't forget that we herewith advise you to limit your forecast to several paragraphs which commit you to nothing—the type of verbose ambiguity which sounds good, but actually boils down to an incongruous jumble of irrelevant considerations. (2) On the other hand, when the accuracy of your comments cannot be questioned, be (and in this connection we use the word with fear and only after fasting) precise. A known statistic or one that can't be checked should be quoted to the last decimal place, not rounded off to an easily remembered number; for example, reports of 1880 showed 275,545 cows in the state of Minnesota.

Our Forecast.—Some experts are predicting that the outlook for 1954 is as glum as a bad mistake. We don't hold with that. Adjustments will occur, surely, but in proper perspective, a moving economy and society require such healthy changes. People will continue to try to get something for nothing, but will gradually become enlightened enough to settle for getting the highest quality something for the lowest price. And if physicians continue a patient and kindly program of enlightening the public about how to get the best medical care for the lowest cost to society, the year's end should show a real gain for the medical profession in the eyes of the public.

H.G.M.

MEDICAL CARE OF DEPENDENTS OF THE ARMED FORCES

When peace is gone and war is nigh,
God and the soldier is the cry.
When war is o'er and peace perfected,
God and the soldier are neglected.

THIS quatrain, so old it must be classed as "traditional" or "anonymous," touches on basic considerations in making up one's mind about medical care for dependents of those in the Armed Forces. It is recalled by the report from the Washington Office of the American Medical Association that a committee of admirals and generals recommend more medical care of dependents.

The report says a five-man committee believes that a serious deterioration of career service can be halted only by such things as higher military pay and more medical and dental care for dependents. Further, Assistant Secretary of Defense John Hannah warns that the services are losing career men in numbers "so great as to be disturbing." Secretary Hannah also cites low military pay and a "continual nibbling away at fringe benefits."

The immediate reaction may well be that military pay is already too high; as are taxes. What with this high military pay, why can't members of the Armed Forces pay for medical care like civilians? Well, we can only urge to look at the other side of the coin before you make any decisions:

If military pay is too high, why was, and is, everyone so eager to get out of the services into civilian life "where you can really make some money?" The fact remains that desirable members of the Armed Forces are leaving the services because pay is not high enough. Patriotism, loyalty to a cause, a high sense of duty—these are all well and good as statements of ideals, but day-in-and-day-out pay scale and benefits cut a more realistic and tangible figure to anyone objectively evaluating the pros and cons of making the Armed Forces his career.

The response that the "regulars" are no good anyway requires little rebuttal. One of the reasons that some career service men gave a poor impression during World War II was that the pay scale had been adequate for those men; their competence was a reflection of the pay scale rather than the pay scale's being a result of their ability.

You can't pick and train first rate chiefs of staff, surgeons general and top non-commissioned officers from a crowd of second rate men. You can't expect the crowd from which you intend to pick top-ranking career service men to be anything but overloaded with second raters if you don't pay them adequately.

It's the old story—you get what you pay for. If you want top quality men forming the "regular" framework of the Armed Forces, you must either pay for superior ability or put your hope and trust in finding a group of idealists who are above anything as mundane as pay and benefits.

H.G.M.

THE CANCER DETECTION CENTER

(Continued from Page 49)

valuable. Seventeen per cent of our examinees (all of whom are aged forty-five or over) have had adenomas or polyps of the rectum and lower sigmoid. Among patients who are asymptomatic the determination of occult blood in the stool has not been worth the laboratory expense and effort entailed. Careful visual examination of the vagina, and cervix, and bi-manual palpation of the pelvis have been rewarding in finding female pelvic malignancies. Five ovarian carcinomas have been detected and all were localized and confined to the ovary at the time of surgery. These women are all well at this time.

For the general public, the practicing physician is and always will be the key person in the diagnosis of cancer. A most important aspect of the Cancer Detection Center program is the evaluation and standardization of procedures which can be applied by physicians generally. We believe that physicians should continue to strive for wider application of cancer detection examination plans. Our Cancer Detection Center is eager to cooperate with them in so doing.

IMPORTANT ACTIONS TAKEN AT AMA SESSION

The House of Delegates of the American Medical Association, meeting at the Jefferson Hotel in St. Louis, during the Seventh Annual Clinical Session, took important policy actions on social security, voluntary health insurance, medical ethics and unethical practices, medical education, hospital accreditation, military affairs and a wide variety of subjects affecting both physicians and the public.

G. P. of the Year

Highlight of the opening session of the House on December 1 was the announcement that Dr. Joseph I. Greenwell of New Haven, Kentucky, had been selected as the 1953 "General Practitioner of the Year."

The first day of the meeting also featured addresses by several Association officers, and annual reports from the Board of Trustees, the Secretary and General Manager and by standing and special committees of the House.

Compulsory Coverage Hit

Approving a recommendation by its Reference Committee on Legislation and Public Relations, the House passed a resolution reaffirming its opposition to the compulsory coverage of physicians under the Old Age and Survivors Insurance provisions of the Social Security Act, and advocating passage of the Jenkins-Keogh bills now pending in Congress. These bills were described as providing for "the development of a voluntary pension program which is equitable, free from compulsion, and satisfies the retirement needs of physicians."

The reference committee report adopted by the House said:

> "The purpose of these bills is to eliminate the discrimination, and inequities which exist under present tax laws by extending the tax deferment privilege to the country's ten million self-employed and also to millions of employes who are not covered by pension plans. The purpose of the resolution is to reaffirm our support of the voluntary pension program provided in the Jenkins-Keogh bills and to reaffirm our strong opposition to the extension of compulsory coverage of physicians and other self-employed persons under Title II of the Social Security Act."

Bricker Amendment Supported

The same committee report urged continued action to obtain passage of the Bricker Amendment (S. J. Res. 1) and approved the principle of legislation which would reduce or remove the limitation on the deduction of medical and dental expenses for income tax purposes. The Bricker Amendment would outlaw any treaties which supersede the Constitution of the United States. The report also opposed any further extension of the "Doctor Draft" Law beyond the present expiration date of June 30, 1955.

On the "Doctor Draft" Law, the report stated that "your Committee feels strongly that there should be no further extension of the 'Doctor Draft' Law. We feel that the legislation is discriminatory and urge the Committee on Legislation and the Board of Trustees to actively oppose any further extension." AMA had recommended that the law be extended for only one year, when it expired on June 30, 1953.

Health Insurance Discussed

The House acted to accelerate the development of voluntary health insurance by passing a resolution requesting the Council on Medical Service to proceed immediately with a special study of the problems of catastrophic coverage and coverage for retired persons. The Council was asked to present its findings and recommendations to the House not later than the 1954 Clinical Meeting. The resolution pointed out:

> "There are two large groups of citizens for whom improved coverage could be offered under present pre-

paid medical care plans, namely: (a) those individuals who suffer catastrophic or long-continued and highly expensive illness and whose financial resources are not adequate to meet the cost thereof and (b) those citizens who have retired and are living on small incomes and who are not eligible under presently existing public or private plans."

The resolution emphasized the medical profession's "responsibility to make every effort to promote such prepaid medical coverage for all citizens whose circumstances make them eligible."

Another resolution on voluntary health insurance, adjudged to be emergency business by the Reference Committee on Insurance and Medical Service and then passed by the House, stated that "the American Medical Association condemns all insurance contracts which classify any medical service as a hospital service."

The resolution was the result of information received that Health Service, Inc., a capital stock casualty insurance company owned by the national Blue Cross Commission, had issued insurance contracts containing medical benefits as well as hospital benefits, to employes of the meat packing industry on a national basis. The resolution stated that this was in violation of principles set forth by the House which define pathology, radiology, anesthesiology and physiatry as medical services.

A further statement in the resolution said: "this continued disregard becomes even more disturbing in view of the fact that Medical Indemnity of America, Inc., an insurance company said to be owned and controlled by Blue Shield Medical Care Plans, Inc., and Health Service, Inc., are operated under an agreement whereby each insurer assumes half of the risk underwritten by the other."

Ethics' Problems Studied

A resolution introduced by the Iowa State Medical Society, calling for approval of a joint-billing procedure involving services rendered by two or more physicians, was referred to the Judicial Council, at the suggestion of the Reference Committee on Miscellaneous Business, with the recommendation "that the Judicial Council investigate the factors involved in the matter as presented and determine if there are new factors or new facets that would cause it to change the opinion" determined in 1952.

In an effort to solve the publicity problems resulting from unethical practices by a small minority of doctors, the House referred to the Board of Trustees a resolution calling for appointment of a special committee with broad professional representation to study all aspects of the problems. The Board was asked to study and implement the intent of the resolution and to report its findings to the House at the June, 1954, meeting in San Francisco.

Dues Picture Clarified

Because of confusion on AMA dues which has resulted since the House began the practice several years ago, the delegates passed the following resolution, which clarifies the situation considerably:

> "Resolved, that any active member of the American Medical Association who failed to pay dues for the year 1950, and who was suspended for such delinquency, may be reinstated during the first six months of 1954 by the payment of 1954 dues only.
>
> "Should such an individual fail to pay his 1954 dues by July 1, 1954, he shall continue to be considered delinquent."

This resolution was substituted for one on the same subject which was introduced by Minnesota's delegates in June, 1953.

To clarify misunderstandings among physicians regarding the rules and regulations of the Joint Commission on Accreditation of Hospitals, especially as they concern the role of the Department of General Practice in a hospital, the House adopted the following resolution:

> "That this House of Delegates of the American Medical Association request the Joint Commission on Accreditation of Hospitals to publish an article, or series of articles, in the *Journal of the American Medical Association* and other official publications circulating among the medical and hospital professions, to acquaint the medical-hospital profession with the regulations, by-laws and their interpretations, and
>
> "That the Commission clarify the methods by which an aggrieved hospital or its staff may appeal a decision with which they are not in agreement."

Education Fund Bolstered

The House was "pleased to note" that a fourth grant of $500,000 had been made by the American Medical Association to the American Medical Education Foundation for financial aid to the nation's medical schools. The Foundation reported that its 1953 income now totals $1,174,000 and that the number of contributors is now more than double the total in 1952.

Dr. Louis H. Bauer of New York, immediate past president of the AMA, was elected president of the Foundation just prior to the opening of the Clinical Session.

PR CONFERENCE DRAWS MANY

The Public Relations Conference, held the day before the Clinical Session of the AMA in St. Louis, was well attended by doctors interested in public relations and medical society personnel from all over the country. Those present heard many interesting and informative discussions on such topics as making a PR program work, what motivates the public's feelings toward medicine, selling the American economic system and how others do it, and mending PR fences.

One of the many talks presented that day was one by Mr. Roger Fleming, Secretary-Treasurer of the American Farm Bureau Federation. Mr. Fleming spoke on how the American Farm Bureau Federation informs the public about its program and its position on price controls.

He emphasized that simply because an organization happens to have taken a negative position on a matter, there is no reason to be ashamed and defensive about it. Illustrating, he stated that one of the most effective "programs" of all time has been the Ten Commandments, and that seven out of the ten begin with "thou shalt not."

Mr. Fleming also pointed out that Paul Revere and the rest of the early Americans were against something—they were against anything that was against freedom. "And that is the position of the Farm Bureau," he stated.

In conclusion Mr. Fleming sited the simile of the fruit growers in a certain state spraying their apples to prevent coddling moths from devouring them completely. It was not a matter of disliking moths so much, he stated, as it was a matter of liking apples so well.

FEDERAL SCHOLARSHIP LEGISLATION READY

The Defense Department's draft legislation for medical and other federal scholarships has received final checking over before presentation to the Budget Bureau for approval, according to a recent issue of the AMA Washington Letter. Budget Bureau approval is necessary if the plan is to be presented as an administration bill, but regardless of the bureau's action, the proposal could be offered by any member of Congress.

The plan provides:

1. Any medical, dental, nursing, or veterinary student accepting a scholarship would be obligated for one year of federal service for each scholarship year.

2. Payment would be made directly to the schools for tuition and other incidentals and to the student to cover living expenses during the school year.

3. Scholarships, limited to four years, would not be offered to pre-medical students or others preparing for professional courses.

4. Deans would make recommendations, but final selection would be by the Defense Department.

Department spokesmen explain that there are two objectives of the plan: first, to meet armed forces' needs after expiration of the doctor draft in 1955, if the regular draft obligation does not produce enough officers. Second, to interest enough young officers in regular military careers to maintain the regular corps at the necessary level. Currently regular medical officers make up only about 25 per cent of the medical corps total; it is hoped to reverse this ratio.

In regard to these federally subsidized scholarships, the AMA House of Delegates, at the Clinical Session in December, considered an emergency resolution which would have endorsed the principle of the scholarships. The resolution was discussed by a House reference committee, which recommended that the matter be referred to the Board of Trustees for study and action. The delegates approved this action unanimously.

HEPATITIS INCREASING

Infectious hepatitis (jaundice) is increasing in Minnesota as well as throughout the United States. To mid-December, 1953, 875 cases had been reported to the State Department of Health. Apparently no part of Minnesota is free from the disease, but it has been reported more frequently from some areas than from others. This difference may represent better reporting by physicians in the areas from which most cases are reported.

Early symptoms of infectious hepatitis include fever, nausea with or without vomiting, loss of appetite, fatigue, lassitude, headache, and abdominal discomfort.

Gamma globulin is reported to be effective in preventing infection in contacts where there is prolonged exposure. The Minnesota Department of Health supplies this material in limited quantities for family contacts of cases. A comparatively small dose is required for this protection—From *Minnesota Health*, January, 1954.

History of Medicine In Minnesota

MEDICAL HISTORY OF THE COUNTY OF YELLOW MEDICINE

MILDRED B. LEE
Granite Falls, Minnesota

(Continued from December, 1953, issue)

John Thomas Gill was born February 26, 1858, at Monroeville, Ohio, the son of Edward and Esther (Young) Gill. His father was a native of the Isle of Man, and had followed the trade of ship's carpenter. He had also helped in surveying the first railroad to be built on the Isthmus of Panama. Esther Gill was a native of Ohio.

John Thomas Gill was the fifth child in a family of nine children, and attended the public schools of Monroeville, Ohio. On completing his high school course he entered Western Reserve College at Cleveland, Ohio, then went to New York Medical College for his medical training, graduating in 1886. Two brothers, William and George, and a sister, Mary Gill, also chose medicine as a profession.

After receiving his degree in medicine Dr. Gill returned to Monroeville where he practiced medicine for four years. At the end of that time he went to Kansas City and practiced for a time in connection with the Cherry Street Hospital there. Following this experience he practiced in Chicago for two years. In 1895 he decided to look for a location in the west, and with Appleton, Minnesota, as his destination he chose a route through Yellow Medicine County over the Minnesota and St. Louis railroad. It was midwinter, and when the train reached Echo it was stalled by blizzard which tied up all rail traffic in the area. The passengers secured what accommodations were offered by the tiny settlement, Dr. Gill securing a room at the Nicollet House.

Word that a doctor was in town soon spread throughout the community, and before many hours had passed Dr. Gill was sought out by a man who was the father of two very sick children. At the farm home Dr. Gill found two little girls ill with diphtheria, one already beyond his help; from that time on Dr. Gill was in constant demand, and by the time the epidemic of diphtheria was past he had made up his mind to remain in Echo.

On October 9, 1896, Dr. Gill was united in marriage with Blanche McClure, who was a native of Seaforth, Ontario, Canada, but had been in Yellow Medicine County since 1894. After their marriage they resided in a small frame house in the business district of Echo and he had his office there for many years.

In appearance Dr. Gill was a slender, wiry, small-boned man of medium height with dark hair and dark eyes which were his most arresting feature. He was friendly, soft-spoken, but nevertheless a man of strong convictions; quick in his movements, decisive in action. His manner was unassuming, quiet, and kindly. He was everybody's friend, devoted to his patients, maintaining a high standard of medical practice and at the same time finding opportunities to take part in civic affairs for the betterment of the community.

In the course of his life in Echo he served as a member of the village council, and as a health officer, and as a member of the school board. He also became a member of the Masonic Order.

Dr. Gill never refused a call. In his first years in Echo he hired a livery rig to take him on his country calls. Later he had his own team and buggy or cutter, and when automobiles came into general use he became the owner of a small car. Thus equipped he would brave any kind of weather, at any cost to himself, and often his pay for this gruelling service would be in the form of a quarter of beef, a load of wood, a dressed goose, or just a word of thanks. Dr. Gill had great sympathy for the needy; he gave freely not only of his medical skill but of whatever he could of material help. Many times Mrs. Gill and her daughters made baby clothes and bought infant's shirts for some needy expectant mother. His daughter Dorothy says, "I can still see him going off with a bundle of baby clothes under one arm, and a toy for an older child in another. He taught his own children that to get the most out of life you had to share with your neighbor. He personally loved every baby he delivered, and there were hundreds of them."

Dr. Gill was, in his quiet way, intensely patriotic. At the beginning of World War I he took an active part in arranging patriotic meetings. His son, Edward, was one of those who were killed in action in that war, and brought home for burial in native soil.

As the years passed, nine children were born to Dr. and Mrs. Gill, grew up, and were educated in the local schools. As Dr. Gill grew older there was no slackening of his efforts to take care of the health problems of the community. During World War I he bought a house in Echo which he equipped as a sort of hospital, or nursing home, for his patients. In later years he took many of his patients to Redwood Falls Hospital. His daughter Esther became a nurse, the only one of his children showing his own inclination to service in the field of medicine.

In February, 1938, some of the people of Echo undertook to make a public show of appreciation for the doctor who had served them so tirelessly and devotedly for forty-three years. They planned a surprise party of grand proportions to be held at the auditorium on a Sunday afternoon, with a suitable gift to be presented to the guest of honor. But on February 21 Dr. Gill received a call from a country patient. Unable to locate his son Robert, who now drove for him, he decided he would go alone, as the Koecher home to which he was called was only two miles from Echo. He reached the home, attended to the needs of his patient, and started back again in his little car. The roads were partially blocked with snow, and Mr. Koecher therefore followed the doctor's car with team and wagon to see that he got safely through the bad places in the road; and when the car stalled he went to help the doctor put additional "snow links" on the wheels. Mr. Koecher had finished putting them on one side, then walked around the car to find the doctor lifeless in the snow.

It was found that death came as a result of a heart attack.

The doctor was survived by his wife and seven children. One child, a son, had died in infancy; Edward was killed in the first World War. The children surviving were James, Crystal (Mrs. P. E. Long), Margaret (Mrs. Fred Norton), Almona, Robert, Esther, Dorothy (Mrs. Carl Sorenson); also eight grandchildren.

The following obituary appeared in the February 25 issue of the *Echo Enterprise,* of Echo, Minnesota.

JOHN THOMAS GILL

His Death Came Suddenly, Without Warning,
Taking from Us Our Best Beloved Citizen.
The Entire Community Mourns.

Our village was stunned and shocked on Monday when word flashed around town that our best beloved citizen, Dr. John T. Gill, had suddenly passed away while making a call to the Fred Koecher home two miles southwest of Echo. The doctor was very busy that morning, and not being able to locate his son, Robert, when ready to start, decided to make the short drive alone. He had reached the Koecher home but before starting back they had placed two snow links upon each of the wheels. Mr. Koecher accompanied the doctor but just before reaching the highway 67 the car stalled. The two men got out to put an extra link upon the wheels. Mr. Koecher had got his link on and upon walking around to the other side of the car saw the doctor slumped over, dead.

Mr. Koecher who had followed the car with his team was obliged to drive back home to summon his son, Fred, Jr., who in turn contacted Alfred Bode and Robert Gill and drove to the scene of the trouble.

The hearse was then secured and the body brought to the mortuary rooms.

The doctor, as the most familiar figure in Echo over this wide span of years, will be sadly missed. Throughout his long residence here as a country doctor he had always stood ready, in all kinds of weather, to answer sick calls and administer to the need. He alone had visited more homes than any other resident, and was always on hand when needed. We join with citizens in general in paying just tribute to this worthy man and doctor. His will be a link in the lives of Echo citizens that will be hard to fill.

In the early days when this country was sparsely settled, and it was necessary to make long trips over the prairie, even in the winter time, with a cutter or bob sled, he never refused to respond to a call.

John T. Gill was born at Monroeville, Ohio, February 26, 1858, where he grew to manhood. After finishing the high school course in his home town, he attended the Western Reserve College at Cleveland and the New York Medical College at New York, graduating in 1886. He returned to his home town and practiced four years. He then went to Kansas City, Missouri, and practiced two years in the Cherry Street hospital. After two years in Chicago he came to Echo in 1895, where he has practiced his profession for the past forty-three years.

Dr. Gill was married October 9, 1895, to Miss Blanche McClure, the ceremony taking place at Redwood Falls. Mrs. Gill came to Echo in 1894 from Seaforth, Ontario, Canada. The widow and seven children survive, namely, James, Mrs. P. E. Long (Crystal) and Mrs. Fred Norton (Margaret) all of Minneapolis, Almona and Robert of Echo, Esther of Detroit, Mich., Mrs. Carl Sorenson (Dorothy) of Tyler. Edward Gill was a victim of the World War, dying in France with burial in Echo cemetery. One son died in infancy. Eight grandchildren also survive. Dr. Gill was a member of the Masonic order. He had served on the village council and school board and was health officer. The parents of Dr. Gill were Edward and Esther Young Gill. The father was born in the Isle of Man, and the mother in Ohio. They passed away in 1920 and in 1912. Mr. Gill Senior was a ship carpenter by trade, and helped survey the first railroad on the Isthmus of Panama. John T. Gill was the 5th child of a family of nine children. Surviving brothers and sisters were Dr. Mary Hunter and Miss Ruth Gill, of Grand Junction, Colo., Miss Bertha Gill, Ypsilanti, Mich., Dr. William Gill, Norwalk, Ohio, Dr. George Gill, Elyria, Ohio, Ernest Gill, Redondo Beach, California. Three sisters preceded him in death.

Dr. W. R. Alexander, pastor of the Presbyterian Church at Vesta, will officiate at the service at one-thirty at the auditorium.

Edward Henry Kerkhoff was born on May 13, 1872, on a farm in Spring Hill Township in Stearns County, Minnesota, about eight miles from Melrose. He was the son of Conrad Kerkhoff who was a native of Lippstadt, Westphalia, Germany, and Catherine Horner Kerkhoff, a native of Stuttgart in Wurttemberg, Germany. The parents had come to the United States and settled first in Wisconsin, then in Minnesota. In 1884 they settled on a farm near Melrose and Edward attended school there. After finishing his studies he took up telegraphy, but about 1894 he made up his mind to study medicine, enrolling in the old Hamline University Medical Department (Minneapolis College of Physicians and Surgeons). He completed his studies and graduated in 1899, but he had been licensed to practice medicine on June 16, 1898.

Early in June, 1898, Dr. Kerkhoff went to Clarkfield with the intention of locating there, as shown by the following announcement of the *Clarkfield Advocate,* on June 2, 1898:

> "Dr. E. H. Kerkhoff came up from Minneapolis last Friday and is now permanently located in Clarkfield. The doctor comes very well recommended, is a very pleasant gentleman to meet, and we predict success for him in our midst. He can be found at the drug store or Commercial House for the present. For the benefit of those who do not speak English we will state that the doctor can converse in both Skandinavian and German."

At the time of Dr. Kerkhoff's arrival in Clarkfield there were two other doctors in residence there; Dr. Albert R. Torgersen, a pioneer physician of the county, and Dr. J. Woodbury Donnell who was county coroner and also county physician. Dr. Donnell was a single man, often depressed and moody. He drank heavily at times, and his manner was not one to inspire confidence. Consequently he was not very successful in establishing a practice in Clarkfield, and spent most of his time helping out in the drug store.

On June 16, Dr. Kerkhoff was asked to make a professional call upon Dr. Donnell. On arriving at the doctor's rooms over the Clarkfield Drug Store Dr. Kerkhoff found Dr. Donnell lying in bed, bleeding profusely from a wound in the throat which he had inflicted upon himself with a pair of scissors. He was also in the throes of convulsions due to a dose of strychnine, also self-administered. In an attempt to save Dr. Donnell's life Dr. Kerkhoff quickly summoned help and endeavored to sew up the wound in the throat, but the patient died within a few hours.

In November Dr. Kerkhoff decided to leave Clarkfield. The *Clarkfield Advocate* of November 10, 1898, announced:

> "Dr. E. H. Kerkhoff left last Saturday for Minneapolis where he will enter the City Hospital for the purpose of improving himself in his chosen profession. During his stay in Clarkfield the doctor made many fast friends, all of whom will greatly miss him. It is hoped that he will again locate in this village when he has finished his hospital service."

After completing his internship at the Minneapolis City Hospital Dr. Kerkhoff was for a short time in Kasson, then in Plainview (Wabasha County). On December 19, 1899, he settled in Pierz, Minnesota, where he continued to practice until his death.

In 1904, Dr. Kerkhoff was married to Miss Rose Vorath, of Agram Township in Morrison County, near Pierz. There were two children born of this marriage.

In 1906 Dr. Kerkhoff practiced for a time in Richmond, Stearns County, but returned to Pierz within a few months. In addition to his medical practice he edited the *Pierz Journal* and was very much interested in farming.

Dr. Kerkhoff was known as a physician who was devoted to his patients and tireless in their service. He was exceptionally well read and interested in many fields outside the practice of medicine. His devotion to his patients caused him to continue caring for them during the pandemic of influenza which followed the first World War, although he himself had been ill for several weeks and was not well enough to resist the disease. He became ill with influenza, complicated by pneumonia, and he died in Pierz on November 15, 1918, at the age of forty-eight years.

John S. Kilbride, son of Michael and Mary (Quinn) Kilbride, was born in the village of Zwingle in Jackson County, Iowa, on December 23, 1865. His father and mother were born in County Roscommon, Ireland, where the Kilbride family had lived for many generations and worked in the trades of weaving and spinning in the Belfast district. Mary Quinn Kilbride was born in County Mayo, Ireland. Michael Kilbride and Mary Quinn came to the United States as young people, and met and were married at Chilicothe, Ohio. After their marriage they moved to eastern Iowa, and then to Havana, Illinois. They came to Jackson County, Iowa, about 1865. Three brothers of Mary Quinn had been killed in the Civil War. In Jackson county the Kilbrides prospered, and they acquired a farm of four hundred acres. Four children were born to them, the oldest of whom was John S. Kilbride. Michael Kilbride died at an early age, when the children were small. Mrs. Kilbride married again, and the stepfather was highly esteemed and respected by the children.

John S. Kilbride grew up in Jackson County, living on a farm and attending country schools. He also had a course at the State Academy at Iowa City, then went to Minneapolis where he attended Central High School, working for his board and other expenses. In the summer he did farm work, or any kind of work he could get.

For his medical training Dr. Kilbride entered the University of Illinois School of Medicine in Chicago, and graduated in 1893. He began his medical practice at Dawson, in Lac qui Parle County, Minnesota.

In the fall of 1894, a pretty young woman by the name of Jennie Spragg came from Milwaukee to teach school at Dawson, and shortly became ill with pneumonia. Dr. Kilbride was called to attend her, and it soon became apparent that she was a very sick girl. Dr. Kilbride was determined to save her; he was almost constantly at the house, neglecting all other calls to devote his efforts to her recovery. His efforts were rewarded; not only did she recover, but she became his wife, the mother of four children: Stephen, who died in infancy, Edward A., Linnae, and Zylpha.

In 1897 Dr. Kilbride took additional medical training, then practiced for a short time in Sleepy Eye. In 1900, he located in Canby.

From the first years of his practice Dr. Kilbride showed exceptional skill and aptitude for the practice of medicine. In his first years at Dawson he earned a reputation for quick and correct diagnosis and treatment. An instance is related of a young man suddenly stricken with appendicitis; Dr. Kilbride lost no time, but operated on the patient on a kitchen table, and removed an appendix already ruptured; the patient recovered. Again, cholera morbus which had claimed many small lives in Dawson, was promptly treated by Dr. Kilbride with unfailing success. His devotion to his patients in that community is still gratefully remembered.

A misfortune that befell the second son, Linnae, in Canby, weighed heavily on the doctor's mind for many years. The railroad had a turntable at Canby; in legal parlance, classed as an "attractive nuisance" in that children were so often drawn to them as a playground. Returning from a professional call one evening the doctor espied his two young sons playing around, and he took them home, and warned the maid and their mother about letting them play away from home. Then he left for his office. Within a short time the little boys were out of the house and back at play; this time they ventured on to the turn table, and Linnae's leg was so crushed that it became necessary to amputate it. Dr. Kilbride was a man of deep feeling, Irish temper and temperament, and he never got over feeling that the accident should have been prevented.

Mrs. Kilbride died August 16, 1908.

Dr. Kilbride was a general practitioner, but he also was a specialist in eye, ear, nose and throat surgery and skin diseases. He kept up with all developments in the field of medicine and attended clinics in medical centers both at home and abroad. In 1910 he went to Germany and studied for a year at the Zeugniss University, afterward touring Europe and visiting the birthplaces of his parents in Ireland. In 1911 he returned to Canby and sold his practice there to Dr. Field, then located in Watertown, South Dakota, where he practiced for four years.

During his residence at Watertown he married again, his second wife Marie being a former resident of Hastings, Minnesota. Of this marriage there was one child, a daughter, Kathleen. The second Mrs. Kilbride was a stately, handsome woman and a Catholic.

In 1915 Dr. Kilbride returned to Canby and formed a partnership with Dr. L. J. Holmberg. This association continued until 1936, when Dr. Kilbride sold his interest to Dr. Holmberg and went to Worthington to practice with his son, Dr. Edwin. In 1943 Dr. Kilbride returned to Canby and established an office in his home, and practiced until the end of World War II, when he returned to Worthington.

In December, 1949, he was severely injured in an automobile accident, and never recovered from it. As a result of his injuries he suffered kidney trouble with complications; loss of vision, and other difficulties. He was treated at Rochester, Minnesota, but rapidly failed and died May 26, 1950, at the Kilbride Hospital in Worthington.

Dr. Kilbride was survived by his four children, Dr. Edwin A. Kilbride of Worthington, Attorney Linnae of Hastings, Zylpha, wife of Stanford Clinton, an attorney, of Chicago, and Kathleen, wife of Nelton Knoop, of Des Plaines, Illinois.

Dr. Kilbride was a Democrat, a member of the Catholic church, and of the Holy Redeemers Council of the Knights of Columbus at Marshall, Minnesota. He was a member of the Minnesota State and American Medical Associations, and was at one time President of the Camp Release Medical Society. He was interested in agriculture, and owned several farms in Yellow Medicine County.

Dr. Kilbride's obituary appeared in the *Canby News*, June 2, 1950.

> "Dr. John S. Kilbride, 84, physician and surgeon in Canby for 32 years, died in the Kilbride Hospital at Worthington Monday night.
>
> Dr. Kilbride, who had been living with his son, Dr. Edwin Kilbride in Worthington since 1945, had been seriously injured in an automobile accident shortly before Christmas, 1949, sustaining a partial rupture of his stomach, and never fully recovered, and had failed rapidly recently. He had lost much of his vision before his death.
>
> Funeral services took place at a Worthington funeral home this morning (Thursday) and burial was made in the Worthington cemetery.
>
> Born in Iowa, December 23, 1864, he grew up in Dubuque and following his graduation from medical school began practicing in Dawson in 1898. After a year there he went to Sleepy Eye and practiced there for a year before coming to Canby in 1900.
>
> In 1910 he went to Germany and studied for a year, and on his return sold his practice here to Dr. Field, and established an office at Watertown, South Dakota, where he practiced for four years. In 1915 he and Dr. L. J. Holmberg formed a partnership here which continued until 1936, when Dr. Kilbride sold his interest to Dr. Holmberg and formed a partnership with his son in Worthington. In 1943 Dr. Kilbride returned to Canby and established an office in his home and practiced until the war ended, returning to Worthington in 1945.
>
> Surviving are four children; Dr. Edwin in Worthington, Attorney Linnae in Hastings, Zylpha in Evanston, Ill., and Kathleen (Mrs. Nelton Knoop) in Des Plaines, Ill."

Dr. Thomas McKey graduated from the Chicago Medical College in 1878. He then took a postgraduate course at the State University of Iowa City, Iowa, in surgery, under Professor W. F. Peck. He completed his course and received another diploma from that institution in March, 1882.

Dr. McKay's medical practice was begun in Merrill, Wisconsin. He was appointed surgeon of the Waupun Prison in 1883, and remained there until 1885 when he moved to Luverne, Minnesota. After a residence of six months in that place he removed to Clear Lake, South Dakota, and practiced there for ten years. In 1896 he located at Canby, Minnesota.

Dr. McKey was a man of average height and very corpulent, weighing in the neighborhood of 250 pounds. He was a pleasant man to meet, friendly and jovial, and made many friends. He was considered to be a very good doctor and he enjoyed a good practice while in Canby. Both the Doctor and Mrs. McKey were very well liked, and they had several children. So far as is known they had no church affiliations in Canby, but Dr. McKey was one of the first officers of Cassiopea Camp, Royal Neighbors, organized in Canby in 1899.

Dr. McKey remained in Canby until after 1900, and then went to Albert Lea, Minnesota.

Dr. M. G. McLean. Nothing is known about Dr. M. G. McLean aside from the fact that he was located in Canby for a few years prior to 1881, and served as coroner in 1878. His period of residence covered about the same period as that of Dr. Billington but there are few who remember anything about him, and as there is no record of his practice it is possible that he was not a graduate with a medical degree. He was, however, recognized as a physician by the county board, which at its meeting in March, 1877, allowed a bill of Dr. M: G. McLean for $2.00 for medical attention to the poor.

Dr. McLean took into parnership Dr. Herman E. Farnsworth in 1880, and the firm is mentioned in Rose's History of Yellow Medicine County in connection with the case of Michael J. Dowling, victim of the storm of October 15, 1880.

James McPeek was born in Indianapolis, Indiana, on March 5, 1852. He was the son of Thomas McPeek, a native of Indiana, and Sahara Barto McPeek who was born in Maine of French Huguenot stock. The family removed to Olmsted County, Minnesota, about 1855 and settled on a farm near Byron, where the boy grew up and attended the public schools of the county.

On December 24, 1875, James McPeek married Miss Ruth Ann Stevens. Some years later he decided to study medicine, and enrolled in the Keokuk College of Physicians and Surgeons in Iowa, graduating in 1889. Following this, and possibly for some time prior to his graduation, he practiced medicine in Gary, South Dakota.

When Dr. McPeek decided to locate in Canby, Yellow Medicine County, there were five McPeek children: Maude, George, Earl, DeEtte, and Sadie. In the spring of 1891 Dr. McPeek purchased, in partnership with O. M. Eichinger, the Adolph Gilberson drug store in Canby, and moved his family into the O. N. Lund house. At this time Mrs. McPeek was in poor health, and accompanied by daughter Maude she went to the home of her mother at Owatonna. In October it was found that her ailment was incurable, and she died in January, 1892, and was buried at Owatonna.

For a time the McPeek family was broken up, some of the younger children being placed with relatives. During this period Dr. McPeek was away on business for the drug store and personal affairs demanded much attention, so his brother Dr. E. A. McPeek "from the eastern part of the state" came to Canby with the intention of remaining there permanently; but he stayed only a few months.

In the latter part of 1892, the drug firm of McPeek and Eichinger bought out the stock of Dorr and Jenson and consolidated the two businesses. This store was one of those destroyed in the great fire in Canby on September 5, 1893; also it was one of the very few to be insured.

Dr. McPeek continued as a member of the Board of Pensions which met in Gary, South Dakota. He had been licensed to practice in that state on May 25, 1889, and made frequent trips there; the older children also kept their connections there. On September 16, 1893, Dr. McPeek was united in marriage with Mrs. Bessie Eakins, of Gary, a widow who had a son by her former marriage. This boy joined the family at Canby and attended school there, and in 1894, a son was born to Dr. and Mrs. McPeek.

Dr. McPeek was in early middle age when he came to Canby, and was of medium height, inclined to fat. He was genial and likeable, a very friendly man. The second Mrs. McPeek was a woman of striking good looks.

About 1895 Dr. McPeek left Canby to locate at St. Charles, Minnesota. Thereafter he moved to Kasson, about 1898, and in 1899 he moved to Sleepy Eye in Brown County. In 1903 he was located in International Falls, where he became health officer of the town. In 1906 he returned to Gary. In 1912 he was practicing at Breckenridge and was the local surgeon for a railway company there.

In his later years Dr. McPeek lived at Ranier, on Birch Point, Rainy Lake, Minnesota. He died of erysipelas of the face at the home of his daughter, Mrs. Stephen Trageser, of Minneapolis, on December 24, 1922, and was buried at Byron, Minnesota.

(To be continued in the Februrary issue)

RHEUMATIC FEVER AND THE SCHOOL CHILD

The school gives an unusual opportunity to attack rheumatic fever. Certain improvements in school health services are needed to make the best use of this opportunity. These recommendations of the Academy will not only be a better approach to rheumatic fever but to other health problems of children. The alertness of teachers and school nurses can bring to medical attention children with signs and symptoms suggestive of rheumatic fever whose condition might otherwise be overlooked. It is also an opportunity through periodic medical examinations to discover unrecognized damage to the heart and to keep under medical supervision known cases of the disease and to make family studies of rheumatic children. It is an opportunity to teach the principles of healthful living to children who have the disease or who are susceptible.

To aid school health authorities to develop a more rational approach in the control of disease, the Committees on School Health and Rheumatic Fever of the American Academy of Pediatrics recommend: (1) that the school medical examination be improved to aid in more accurate recognition and supervision of rheumatic children, (2) that more emphasis be placed on referral by teachers and nurses of pupils believed to be below-par for medical review, (3) that less emphasis be placed on restricting the physical activity of rheumatic children and more attention given to daily observation of pupils for signs or conditions suggestive of rheumatic disease, (4) that there be available, to school health services and the practitioners, diagnostic and consultation services to establish diagnosis, (5) that these services be developed in co-operation with, and by utilization of, existing medical and public health resources in the community. —From Report of the Committee on School Health and the Committee on Rheumatic Fever of the American Academy of Pediatrics, 1948.

MINNEAPOLIS WOMAN MUST SERVE SIX MONTHS FOR ABORTION

Re. State of Minnesota vs. Annabelle Keith

On December 7, 1953, Mrs. Annabelle Keith, aged twenty-seven, 2805 St. Mary's Place, Minneapolis, was sentenced by the Hon. Theodore B. Knudson, Judge of the District Court of Hennepin County, to a term of not to exceed four years in the Women's Reformatory at Shakopee on an abortion charge, the sentence being stayed, however, and the defendant placed on probation on condition that she serve the first six months of her sentence in the Minneapolis Women's Detention Home. Judge Knudson further provided that Mrs. Keith should begin serving her term on December 29, 1953. The defendant had previously, on October 13, entered a plea of guilty before Judge Knudson to an information charging her with the crime of abortion.

Mrs. Keith was arrested by Minneapolis Police Officers on October 2, 1953, when it was discovered that she had aborted a twenty-four-old Saint Paul divorcee about three weeks previously. The defendant performed the abortion upon the patient who was three and a half months pregnant, by using a catheter and was paid the sum of $50.00 for her services. She is not licensed to practice any form of healing in this state and further admitted that she has had no medical training but claimed to have learned how to do abortions from a Milwaukee, Wisconsin, woman in 1942.

ONE MINNEAPOLIS MAN GIVEN PRISON TERM, ANOTHER PROBATION FOR ABORTION

Re State of Minnesota vs. Paul Schwede and Julius J. Capra

On October 1, 1953, Paul Schwede, forty-nine, 127 West 26th Street, Minneapolis, a meat market operator, was sentenced by the Hon. Theodore B. Knudson, Judge of the District Court of Hennepin County, to a term of not to exceed four years at hard labor in the State Prison at Stillwater for the crime of abortion. Because he was not placed on probation Schwede must serve his sentence

On November 9, 1953, Judge Knudson sentenced Julius J. Capra, thirty-five, a meter reader who resided at 239 Clifton Avenue, Minneapolis, to a three-year prison term on the same charge, the sentence being suspended, however, and the defendant placed on probation for the same period.

Both defendants were arrested in connection with the same case. An investigation disclosed that Capra had given the name and phone number of a twenty-eight-year-old Minneapolis divorcee who was seeking an abortionist, to the defendant Schwede. The abortion was later performed by Schwede, who holds no license to practice any form of healing in Minnesota. Of the $285 that was paid for the abortion Schwede received $200 and Capra was paid $85 for his services in the case. The investigation revealed that Capra had referred other women to Schwede for the same purpose in the past.

The defendant Schwede has a previous conviction for abortion, having been sentenced on June 20, 1950, by the Hon. Rolf Fosseen, Judge of the District Court of Hennepin County, to a term of not to exceed four years in the State Prison at Stillwater on that charge. However, the sentence was stayed for three years and Schwede was placed on probation after he had served three months in the Minneapolis Workhouse. The records of the United States District Court in Minneapolis disclose that on November 4, 1946, Schwede was fined $200 following a plea of nolo contendere to an information charging him with a conspiracy against the United States in connection with the illegal use of counterfeit sugar stamps.

MINNEAPOLIS WOMAN SENTENCED FOR ABORTION

Re State of Minnesota vs. Lois Townsend

On October 30, 1953, the above-named defendant was sentenced by the Hon. Theodore B. Knudson, Judge of the District Court of Hennepin County, to a term of not to exceed four years in the Women's Reformatory at Shakopee on an abortion charge, the sentence being stayed, however, and the defendant placed on probation for the same period of time. She had previously on September 16 entered a plea of guilty before Judge Knudson to an information charging her with that crime.

Miss Townsend, twenty-nine, was charged with having taken medicine, drugs or other substances, and used certain instruments with intent to produce her own miscarriage. She was brought by ambulance on August 21, 1953, from her apartment at 1325 Hawthorne Avenue, Minneapolis, to General Hospital because she was hemorrhaging as a result of an abortion, which medical opinion held to be an induced abortion.

When the police searched Miss Townsend's apartment, they found a bone knitting needle, which had the appearance of a catheter, some quinine, and also a wire such as those that are inserted inside of catheters. In addition they discovered a medical book that had a marker in it on a page which dealt with the subject of abortion. The ownership of the book was traced to a man who had been convicted of abortion in Hennepin County in 1941. When Miss Townsend was questioned by the authorities she denied that an abortion had been performed upon her by anyone, but when it was learned that she had previously stated that she had aborted herself the charge referred to above was placed against her.

◆ Reports and Announcements ◆

INTERNATIONAL ACADEMY OF PROCTOLOGY

The International Academy of Proctology announces its annual cash prize and certificate of Merit Award contest for 1953-1954. The best unpublished contribution on proctology or allied subjects will be awarded $100 and a Certificate of Merit. Certificates will be awarded also to physicians whose entries are deemed of unusual merit. This competition is open to all physicians in all countries, whether or not affiliated with the International Academy of Proctology. The winning contributions will be selected by a board of impartial judges, and all decisions are final.

The formal award of the first prize, and a presentation of other certificates, will be made at the annual convention dinner dance of the Academy in April, 1954. The Academy reserves the right to publish all contributions in its official publication, *The American Journal of Proctology*. All entries are limited to 5,000 words, must be typewritten in English, and submitted in five copies. All entries must be received no later than the first day of February, 1954. Entries should be addressed to the International Academy of Proctology, 43-55 Kissena Blvd., Flushing, New York.

* * *

Physicians are cordially invited to attend the sixth annual convention of the International Academy of Proctology to be held at the Palmer House, Chicago, Illinois, April 8 to 11, 1954.

An extensive motion picture seminar of proctologic surgery (including office techniques) will be held on April 11. All scientific papers will present the latest developments in proctology and gastroenterology.

Because general practitioners as well as gastroenterologists and proctologists, face proctologic problems in their daily practice, much of the program has been planned to answer their questions.

The program will be available upon request to the Executive Office of the International Academy of Proctology, 43-55 Kissena Boulevard, Flushing, New York.

MISSISSIPPI VALLEY MEDICAL SOCIETY 1954 ESSAY CONTEST

In its thirteenth annual essay contest the Mississippi Valley Medical Society will offer a cash prize of $100, a gold medal, and a certificate of award for the best unpublished essay on any subject of general medical interest (including medical economics and education) and of practical value to the general practitioner of medicine. Certificate of merit may also be granted to the physicians whose essays are rated second or third best. Contestants must be members of the American Medical Association and residents and citizens of the United States. The winner will be invited to present his contribution before the nineteenth annual meeting of the Mississippi Valley Medical Society to be held at Chicago, September 23 and 24, 1954. The Society reserves the exclusive right to first publish the essay in its official publication—the *Mississippi Valley Medical Journal.* All contributions shall be typewritten in English in manuscript form, submitted in five copies, not to exceed 5,000 words, and must be received not later than May 1, 1954. The winning essays in the 1953 contest appear in the January, 1954, issue of the *Mississippi Valley Medical Journal.* Further details may be secured from: Harold Swanberg, M.D., secretary, Mississippi Valley Medical Society, 209-224 W. C. U. Building, Quincy, Illinois.

INTERNATIONAL GROUP OF DOCTORS IN ALCOHOLICS ANONYMOUS

The fifth annual International Group of Doctors in Alcoholics Anonymous will meet at the Mayflower Hotel, Akron, Ohio, May 14 to 16, 1954. All physicians interested in this meeting are cordially invited to attend. For information and reservations, address: Doctors, Mayflower Hotel, Akron, Ohio.

MINNESOTA OBSTETRICAL AND GYNECOLOGICAL SOCIETY

New officers of the Minnesota Obstetrical and Gynecological Society were named at a meeting held December 5, at the Hotel Lowry, Saint Paul. Dr. Arnold O. Swenson, Duluth, vice president, succeeds Dr. Arthur B. Hunt, Rochester, as president; Dr. Leonard Lang, Minneapolis, was elected vice president, and Dr. Rodney F. Sturley, Saint Paul, was re-elected secretary-treasurer. Scientific papers were presented during the day sessions, and Dr. LeRoy A. Calkins, professor of obstetrics and gynecology at the University of Kansas Medical Center, Kansas City, Kansas, addressed the group in the evening.

POSTGRADUATE COURSE IN DISEASES OF THE CHEST

A postgraduate course sponsored by the Council on Postgraduate Medical Education of the American College of Chest Physicians will be conducted February 15 to 19, 1954, at New Orleans, Louisiana. The course will be held in conjunction with the Tulane University of Louisiana and the Louisiana State University. Dr. J. Winthrop Peabody is chairman of the postgraduate course committee. For further information, address American College of Chest Physicians, 112 East Chestnut Street, Chicago 11, Illinois.

FAMILY DOCTORS' DAYS

University of Minnesota Hospitals

All physicians are cordially invited to attend the following Family Doctors' Days which will be presented under the direction of the department indicated.

February 17	—	Neurology
March 10	—	Dermatology
April 7	—	Pediatrics

Activities begin with luncheon at 12:00 noon with the staff of the department in the Hospital Dining Room and will continue throughout the afternoon.

For further information, write the head of the department concerned or the Director, Department of Continuation Medical Education, 3330 Powell Hall, University of Minnesota.

(The initial Family Doctors' Day of the year was presented under the direction of the Department of Radiology, January 6, 1954.)

CONTINUATION COURSES

A *Conference on Coroners' Problems* will be presented by the University of Minnesota from March 8 to 10, 1954, at the Center for Continuation Study on the University Campus. Intended primarily for coroners, the course will also be of interest to law enforcement officers and to pathologists. Procedures of help in the investigation of all types of accidental or suspicious deaths will be discussed. The faculty for the course will include Dr. Walter W. Jetter, professor of legal medicine, Boston University, and the program will be presented under the direction of Dr. James McCartney, professor, department of pathology, University of Minnesota Medical School.

* * *

A continuation course in *Eye, Ear, Nose, and Throat for General Physicians* will be presented April 5 to 7 by the University of Minnesota at the Center for Continuation Study. The management of common problems involving the eyes, ears, and upper respiratory tract will be stressed. The course will be presented under the direction of Drs. L. R. Boies, Clinical Professor and Head, Department of Ophthalmology and Otolaryngology, and Erling W. Hansen, Clinical Professor and Director, Division of Ophthalmology. They will be joined by members of the clinical faculty of the University of Minnesota.

* * *

The University of Minnesota will present a continuation course in *Urology for General Physicians,* April 8 to 10, 1954, at the Center for Continuation Study. Common urological problems encountered by the physician in general practice will be discussed in detail. The course will be presented under the direction of Dr. C. D. Creevy, Professor and Director, Division of Urology, who will be joined by members of the faculty of the University of Minnesota Medical School and the Mayo Foundation.

* * *

Dr. Samuel A. Levine, Clinical Professor, Harvard University Medical School, Boston, will take part in a continuation course in *Cardiovascular Diseases for General Physicians* which will be presented at the Center for Continuation Study on the University of Minnesota Campus, March 22 to 24, 1954. The course, sponsored jointly by the University and the Minnesota Heart Association, will stress management of practical problems in the cardiovascular field. Dr. Levine will also present the annual George E. Fahr Lecture on March 23. The course will be presented under the direction of Dr. C. J. Watson, Professor and Head, Department of Medicine, University of Minnesota Medical School, and the remainder of the faculty will include clinical and full-time members of the faculty of the University of Minnesota Medical School and the Mayo Foundation.

* * *

A continuation course in *Emergency Surgery for General Physicians* will be presented at the Center for Continuation Study, April 1 to 3, 1954. Intended primarily for the physician in general practice, the course will stress the emergency management of various types of trauma and of acute abdominal conditions. The faculty for the course will include Dr. J. Garrott Allen, Professor of Surgery, University of Chicago School of Medicine. He will also deliver the annual Clarence M. Jackson Lecture on the evening of April 1. The program will be presented under the direction of Dr. O. H. Wangensteen, Professor and Chairman, Department of Surgery, with clinical and full-time members of the staff of the University of Minnesota Medical School.

BLUE EARTH VALLEY MEDICAL SOCIETY

Doctors of Martin, Faribault and Watonwan Counties (Blue Earth Valley Medical Society) held their annual meeting at the Presbyterian Church at Blue Earth, November 19, with the following officers elected: Dr. E. J. Bratrude, St. James, president; Dr. R. S. Armstrong, Winnebago, vice president; Dr. H. Boysen, Madelia, secretary-treasurer; Dr. M. P. Virnig, Wells, delegate; Dr. Harold Coulter, Madelia, alternate delegate, and Dr. William J. Hruza, Madelia, member of the board of censors.

RICE COUNTY MEDICAL SOCIETY

Officers of the Rice County Medical Society for 1954 were elected October 20 at Faribault, as follows: Dr. Norman Lende, Faribault, president; Dr. Paul F. Meyer, Faribault, vice president; Dr. Burton A. Orr, Faribault, secretary-treasurer; Dr. James J. Kolars, Faribault, delegate; Dr. R. R. Moses, Kenyon, chairman of censors, with Dr. F. W. Stevenson, Faribault, and Dr. R. F. Mears, Northfield, as the other members of the board of censors.

Committee chairmen for 1954 are: Dr. Burton A. Orr, Faribault, Committee on Military Affairs and Civil Disaster Medical Services; Dr. Heinz H. Bruhl, Faribault, Committee on Education; Dr. Paul F. Meyer, Faribault, Chest Pilot Study and Follow-up; Dr. E. J. Engberg, Faribault, County Medical Advisory Committee on Medical Service; Dr. Paul H. Weaver, Faribault, Committee on Public Health; Dr. Carl A. Traeger, Faribault, Committee on newspaper publications; and Dr. Bernard Street, Northfield, County Medical Advisory Committee to the Welfare Department.

Society meetings will be held regularly on the third Tuesday of each month during 1954.

In Memoriam

LEE WILLIS BARRY

Dr. Lee Willis Barry, long a distinguished Minnesota obstetrician and gynecologist, died at the age of sixty-seven in Fort Lauderdale, Florida, Thursday, December 3, 1953.

Dr. Barry had practiced for nearly thirty-four years in Saint Paul, but had moved his offices to the Minneapolis Medical Arts Building shortly before he died.

As assistant clinical professor of obstetrics and gynecology at the University of Minnesota and as a practitioner, Dr. Barry was a leader for many years in his specialty. He was the first to receive a Ph.D. degree in obstetrics and gynecology at the University of Minnesota.

He was born at Elbridge, Michigan, and received his pre-medical training and medical education at the University of Michigan. After a year's general internship at the St. Francis Hospital in Pittsburgh, Pennsylvania, he spent two years in postgraduate study in pathology at the University of Indiana. After a two-year interval, three additional years of obstetrics and gynecology study were spent at the University of Minnesota, from which he received his advanced degree in 1919. He located in Saint Paul in 1920.

Besides his University affiliation, Dr. Barry was a member of the Ramsey County Medical Society, the Minnesota State Medical Association, the American Medical Association, the Minnesota Academy of Medicine, the Saint Paul Surgical Society and the Minnesota Obstetrical and Gynecological Society. He was a fellow of the American College of Surgeons and the International College of Surgeons, and a diplomate of the American Board of Obstetrics and Gynecology and the American Academy of Obstetrics and Gynecology. He held the post of chief of staff at St. Joseph's Hospital in Saint Paul and was a member of Saint Paul Rotary Club, Sigma Xi and Phi Rho Sigma.

He is survived by his wife, Nora W. Barry; two daughters, Mrs. Harry Skornia, Champaign, Illinois, and Miss Margaret Barry, Minneapolis; one son, Dr. Lee W. Barry, Jr., Saint Paul, a dentist; one sister, Mrs. Russell Thomas, Owasso, Michigan, and three grandchildren. Honorary pall bearers were Drs. Joseph F. Bicek, G. D. Brand, Ben A. Weis, Earl Lowe and C. N. Hensel, all of Saint Paul.

PHILIP FRANCIS DONOHUE

Dr. Philip Francis Donohue, prominent Saint Paul urologist and 1953 president of the Ramsey County Medical Society, died at Miller Hospital in Saint Paul, Thursday, December 17, 1953, at 9:30 p.m., following a heart attack suffered a short time earlier at the St. Paul Curling Club.

Dr. Donohue was fifty-nine years old and had been active in his practice and in his favorite sports up to the time of his death.

He was born in 1895 in Saint Paul, where he attended grade schools, the St. Thomas Academy and Mechanic Arts high school. He took his premedical training at St. Thomas College and the University of Minnesota and received his medical degree from the St. Louis School of Medicine in St. Louis, Missouri. He served his internship at St. John's Hospital in St. Louis and at Miller Hospital in Saint Paul and took his postgraduate training in urology in the Department of Urology at Ancker Hospital, Saint Paul. He practiced his specialty as surgeon and diagnostician for thirty years in Saint Paul, where he served as staff urologist at Ancker, Miller, St. John's, St. Luke's and St. Joseph's Hospitals. He also served as associate professor of urology at the University of Minnesota.

Dr. Donohue was a fellow of the American College of Surgeons and a diplomate of the American Board of Urology, on which he also served as member of the board. He was a member of the North Central Section of the American Urological Association and of the Saint Paul Surgical Society, the Saint Paul Clinical Club, the Saint Paul Medical Forum and the Twin City Urological Society. He was a member of the Ramsey County Medical Society which he served in many capacities besides president, the Minnesota State Medical Association, and the American Medical Association.

Dr. Donohue occupied the old family home at 1481 Summit Avenue. He was an enthusiastic golfer and a member of Saint Paul Rotary Club, and of the Town and Country Club.

He is survived by one brother, John H. Donohue, of Saint Paul, and three sisters, Mrs. Grace Lavery, Evanston, Illinois; Mrs. Edith Dolan, Saint Paul, and Miss Florence Donohue, Pittsburgh, Pennsylvania.

ROBERT CYRUS FARRISH

Dr. Robert Cyrus Farrish died Friday, December 11, 1953, at his home in Sherburn after more than forty years of general practice in the area. He was eighty-six years old and still served occasionally as a consultant at the time of his death.

A community celebration marked his fortieth year of practice in Sherburn in 1950, and hundreds of residents from the entire district, most of whom he had delivered as infants, attended. It was the occasion for many recollections about him as the beloved and trusted country doctor. He was said to have cared for 1,600 cases during the influenza epidemic of 1917 and 1918 during which period he wore out four sets of tires, lost 44 pounds in weight, and drove to exhaustion no less than seven drivers for his car.

Dr. Farrish was born in Rockwood, Ontario, where his father, William Farrish, a Dumfries Scot, had located in the early 1850's. A friend of Empire-builder James

J. Hill, the elder Farrish moved to Saint Paul soon after Dr. Farrish was born in 1869. Dr. Farrish attended Rockwood Academy and then went to work for Hill in Saint Paul to help finance his medical education. He enrolled in the medical school of the University of Minnesota in 1897 and received his degree in 1901. He served his internship at St. Mary's Hospital in Rochester and became surgical assistant there to Dr. Charles H. Mayo. At the time of his death, he was the oldest living intern from St. Mary's.

He was a charter member of the Blue Earth County Medical Society, a member of the Minnesota State Medical Association, of which he became a life member in 1947, and of the American Medical Association. He served as vice president of the Minnesota Association in 1930.

Dr. Farrish went to Sherburn to practice with his brother, Dr. Malcolm Farrish, also a physician, in 1910, and together they maintained offices in Sherburn and Ceylon. After the death of his brother in 1915, Dr. Farrish practiced alone and also operated the Farrish Hospital in Sherburn for many years. In 1920, he married Mrs. Laura Bettenhausen Farrish, his brother's widow, and adopted her three children, the eldest of whom, Mrs. William Luwe, is now a practicing attorney in Mankato. A second daughter married Dr. L. O. Johnson, a Sherburn dentist. The third child is Dr. Robert Malcolm Farrish, a dentist practicing in Litchfield.

Dr. Farrish was a regional medical examiner for the 4-H clubs, and a 32nd degree Mason and member of the Shrine.

He is survived by his wife, three children, a sister, Mrs. L. G. Foley of Saint Paul, and two grandchildren.

HILLARD HERMAN HOLM

Dr. Hillard Herman Holm, for many years a leading surgeon of Glencoe, Minnesota, died following surgery for a stomach ailment at Asbury Hospital in Minneapolis, Thursday, November 19, 1953. He was sixty years old.

Dr. Holm had been active in his practice at Glencoe until a month before he died. He moved there on Valentine's Day of 1920, the day after his marriage to Blanche Laura Rucker of Howard Lake, and remained there continuously for thirty-three years.

He was born at Carver, April 11, 1893, and went to school there. He attended Macalester College where he received his Bachelor of Arts degree in 1915. He received his medical education at the University of Minnesota medical school and served a two-year internship in surgery at Minneapolis General Hospital.

During the earlier years of his practice, Dr. Holm operated his own hospital in Glencoe with the assistance of Mrs. Holm, a registered nurse. He was health officer of Glencoe and McLeod County for a number of years and served as coroner for several terms. He was a leader in civic as well as medical affairs in the community and was a member for many years of the First Congregational Church of Glencoe, the American Legion, the Izaak Walton League and the University of Minnesota Alumni Association.

Among physicians, he was recognized as a skilled surgeon, and he is remembered especially for a successful operation separating Siamese twins which was performed in January, 1927.

Dr. Holm was a fellow of the American College of Surgeons, a member of the Minnesota State Medical Association, the American Medical Association, the McLeod County Medical Society, the American Association of Railway Surgeons and the Milwaukee Road Company Surgeons.

He is survived by his wife; a daughter, Mrs. R. H. Rantala, Fort Worth, Texas; a brother, Harold C. Holm, St. Paul; and two grandchildren, Neil and Erick Rantala of Fort Worth.

Eleven fellow physicians from Glencoe and surrounding communities acted as honorary pallbearers. They were Drs. J. D. Selmo, Norwood; J. J. Smyth, Lester Prairie; A. M. Jensen and G. L. Griebie, Brownton; W. W. Klima, Stewart; Edward G. Olsen, Minneapolis; Charles G. Sheppard, Donald Brink, Walter G. Sahr and E. W. Lippman, Hutchinson; and C. W. Truesdale, Glencoe.

HENRY J. SHELVER

Dr. Henry J. Shelver, who practiced medicine first at Appleton and then in Ortonville for nearly thirty years, died Saturday, January 2, 1954, in the United States Veterans Administration Hospital in Fargo, North Dakota, where he had been a patient for the last three years. Dr. Shelver was sixty-nine years old.

He was educated at Concordia College in Moorhead and at Hamline and Northwestern Universities. He was graduated from the latter in 1910 and served his internship at Swedish Hospital in Minneapolis. After a further period of postgraduate work in Chicago, he opened his practice in Appleton where he remained for eight years before moving to Ortonville.

Until his retirement from active practice, Dr. Shelver was a member of the West Central Medical Society, the Minnesota State Medical Association and the American Medical Association.

Survivors are Mrs. Shelver and a daughter, Mrs. Glenn Crane of Morristown, New Jersey.

◆ Of General Interest ◆

Willow River, without a resident doctor since the death of Dr. W. C. Ehmke in 1948, has secured the services of **Dr. Martin S. Munson,** Barnum, for Tuesdays and Thursdays of each week. Willow River Community Club and Willow River Commercial Club have spent time and effort working out the details of the plan and securing office space for Dr. Munson.

* * *

Dr. Fred Soper, New York City, director for the World Health Organization for the Western Hemisphere, in speaking at the University of Minnesota recently, cited the tremendous strides in helping backward countries help themselves to better health. Most significant has been the development of teams consisting of doctors, engineers, nurses, educators, sanitary inspectors and others who have worked together to fight perennial diseases such as malaria and yellow fever, and solve problems of mother and child health.

* * *

The quarterly new Fellows dinner, November 19, 1953, was held at Balfour Hall of Mayo Foundation House, with more than one hundred physicians in attendance. The dinner was given for new Fellows, and physicians recently returned from military service to complete their fellowships. Speakers were: **Dr. Fredrick A. Willius,** senior consultant in cardiology at the Clinic, who spoke of the heritage and traditions of the Mayo Clinic, and described experiences he had had with the late Dr. Henry S. Plummer; **Dr. Jesse Edwards,** consultant in pathological anatomy at the Clinic, who spoke of the opportunities for Fellows at the Mayo Foundation with regard to research activities, meetings and seminars, and the opportunities of obtaining postgraduate degrees.

Fellows were greeted by **Dr. Clayton H. Klakeg,** vice president of the Fellows Association and master of ceremonies for the program. The following officers were introduced: **Dr. E. V. Johnston,** president; **Dr. J. O. Godden,** secretary, and **Dr. E. B. Waldmann,** treasurer. **Dr. William Manger,** past president of the association, greeted the group also.

A standing ovation was given by **Dr. Donald C. Balfour, Sr.,** emeritus director of the Mayo Foundation, as he expressed his greetings.

* * *

Dr. Paul V. Cumiskey of Mankato, is temporarily working at the Oliver Clinic until a new clinic with which he will be associated in Minneapolis, is completed. Dr. Cumiskey is a graduate of the University of Minnesota, serving his internship at the Fresno County General Hospital.

Dr. M. H. Bauer, Winthrop, was injured by flying glass particles when a stray bullet hit the windshield of the car in which he and his wife were driving through Chaska, November 23. The shatterproof windshield protected him, probably saving his life. Mrs. Bauer was driving at the time of the accident.

* * *

The regents of the University of Minnesota authorized thirty-five new staff appointments, fifty terminations of staff personnel, eighteen promotions and transfers, twenty salary adjustments, twenty-eight leaves of absences, and accepted $28,744 in gifts. Two medical research scientists headed the list of appointments: **Dr. Francisco Grande,** citizen of Spain, will become an associated professor in the laboratory of physiological hygiene at the University, and **Dr. Richard W. Anderson,** psychiatrist from Saint Paul, will become an associated professor in the department of psychiatry and neurology.

* * *

The merits of the Blue Cross and Blue Shield plans were discussed at the Stearns-Benton Medical Society meeting held at St. Cloud, November 19, 1953. **Dr. O. L. M. Nelson,** Minneapolis, a specialist in internal medicine, described cases of psychosomatic factors in treatment of diseases. Attendance prizes were won by **Dr. R. P. Koenig,** Paynesville, **Dr. M. McMahon,** St. Cloud, and **Dr. E. Sherwood,** Kimball.

* * *

The new Seifert-Dupont-Dornbach medical clinic, Excelsior, opened the first of November. The clinic contains some twelve consultation rooms and laboratories, and offices for the three physicians: **Dr. M. H. Seifert, Dr. J. A. Dupont,** and **Dr. Robert Dornbach.**

* * *

Dr. Walter A. Reiling, chief of staff of the Good Samaritan Hospital, Dayton, Ohio, spoke at a general meeting of all Optimist clubs in Minneapolis, December 2. Dr. Reiling is president of Optimist International.

* * *

Dr. John O'Hanlon has opened offices in Edina with **Dr. Harry C. Jensen.** Dr. O'Hanlon is a graduate of Marquette University. He has been in practice in rural areas as well as Minneapolis and Duluth.

* * *

Dr. James Reinhardt, of Detroit Lakes, has been promoted to the rank of captain in the army. Dr. Reinhardt, stationed at James Connally Air Force Base, was surgeon and physician at Alexandria before going into the army.

Dr. Louis Katz, director of cardiovascular research at Michael Reese Hospital, Chicago, and professional lecturer in physiology at the University of Chicago, spoke on the brighter outlook for the victim of blood pressure at Saint Paul Society for Internal Medicine held at the University Club, December 2. **Dr. D. R. Gillespie,** of Saint Paul, is president of the group.

* * *

Dr. Wallace Ritchie, Saint Paul, presented a discussion on head injuries with particular reference to neuro-surgical treatment which the general practitioner can render, at a dinner meeting of the Southwestern area of Minnesota Academy of General Practice. The meeting was held in the Municipal Lounge at Willmar, November 30.

* * *

Dr. M. H. Larson, Nicollet, spoke at a Cancer Workshop held in St. Genevieve's Church, Lake Benton, November 18. Dr. Larson stressed that the doctor's office is the first line of defense against cancer.

* * *

The fiftieth anniversary of the Hennepin County Tuberculosis Association which was organized December 2, 1903, as the Anti-Tuberculosis Committee of the Minneapolis Associated Charities, was celebrated at the Citizens Aid building, Minneapolis, December 2, 1953. **Dr. S. Marx White,** member of the association's executive committee, presided. He also gave a pictorial record of early tuberculosis work in Minneapolis and Hennepin County. "Tuberculosis led all other diseases as a cause of death. One child in every nine died before its first birthday," said Dr. White in commenting on the early work.

Dr. Stewart C. Thomson, professor and assistant director of the University of Minnesota School of Public Health, reviewed the work of a half century in fighting tuberculosis in a talk entitled, "The Building of a Wall."

* * *

Dr. Martin S. Munson, Barnum, has "adopted" Kim Kyong Ja, an eleven-year-old Korean girl, under Foster Parents' Plan for War Children, Inc. The "adoption" is not legal, of course, only financial. The foster parent promises to contribute $15 monthly toward the child's support for one year, receiving in turn a brief history of the child and a photograph as well as correspondence, if possible, to help the child feel that he belongs to someone. "Home" to Kim Kyong Ja is a crowded institution in Kunsan.

* * *

Dr. Herman E. Hilleboe, son of P. S. Hilleboe, Mankato, has been named president-elect of the American Public Health Association. Dr. Hilleboe is state commissioner of health in New York. He will take office as president at the association's annual meeting to be held in Buffalo, New York, October, 1954.

Dr. Frederick W. Wittich, Minneapolis allergy specialist, has been named trustee and member of the executive committee of the newly-formed American Foundation for Allergic Diseases, Inc. This is a nonprofit organization to help promote understanding of allergic diseases, of which, studies have shown, there are 3,900,000 Americans suffering. Dr. Wittich is managing editor of *Annals of Allergy* and editor of the *Quarterly Review of Allergy and Applied Immunology.*

* * *

Dr. and Mrs. Arthur B. Williams, Saint Paul, celebrated their golden wedding anniversary in October. They were married in Rock Rapids, Iowa, October 14, 1903, and lived in Wilmont, Minnesota, where Dr. Williams practiced medicine until he was called into service in World War I. Following the war, the family moved to Worthington, where Dr. Williams practiced for six years, before moving to Saint Paul in 1926.

* * *

Dr. N. R. Kippen has become associated with the Breckenridge Clinic, Breckenridge. Dr. Kippen was graduated from the University of Manitoba in 1948. During the last five years he had further studies in surgery, orthopedic surgery and pathology in Canada.

* * *

Dr. Clinton C. Berg, Dr. Melvin G. Oppen and **Dr. Roger S. Johnson** are engaged in group practice with offices in both Excelsior and Deephaven. The association was formed December 1. Dr. Berg was previously associated with Dr. Lewis Reid of Excelsior. All three doctors are graduates of the School of Medicine, University of Minnesota.

* * *

Dr. Irvine McQuarrie, president of the State Heart Association, and **Dr. Harold S. Diehl,** dean of the University of Minnesota Medical School, were speakers at a luncheon in Coffman Memorial Union, December 5, for volunteer workers in the 1954 Heart fund. The annual fund campaign, to be held in February, with a quota of $210,000, is sponsored by members of the Minnesota State Association of Life Underwriters. A check of $30,000 was presented by the Minnesota Heart Association to Dr. Diehl at the luncheon. This is the second allocation for heart research at the university for 1953.

* * *

Dr. Joseph Brennan, Duluth, spoke at the Park Point Community Club, of Duluth, November 27. Dr. Brennan, born on the island of Malta, was studying medicine in Rome when he was imprisoned by the Italians during World War II. After escaping, he worked with underground groups. He completed his education in Europe and America.

* * *

The new Chisholm Memorial Hospital opened November 2, 1953, with **Dr. P. H. Macfarlane** as head of the staff; **Dr. Clarence Jacobson,** vice president, and **Dr. A. D. Klein,** secretary. Organized on an "open staff" basis, the following doctors are registered with the hospital: **Dr. Joseph L. Arko, Dr. George Doxsee, Dr. George Erickson, Dr. Frank Farley, Dr. Bernard Flynn, Dr. Bayard French, Dr. Bernard Hapler, Dr. Robert Hansen, Dr. H. R. Irwin, Dr. Luverne Johnsrud, Dr. Stanley Lipinski, Dr. Robert Murray, Dr. Wilbert Parker, Dr. Andrew Sinamark, Dr. Carlyle Tingdale,** and **Dr. Wesley Tomhave.**

The thirty-bed hospital has twelve bassinets, operating and delivery room, and laboratory and x-ray facilities.

* * *

Dr. B. J. Kennedy, University of Minnesota, spoke on "Medical and Chemotherapy Treatment for Cancer," at a luncheon meeting of the Ramsey County Cancer Society held at the Athletic Club, Saint Paul, November 18.

* * *

Dr. H. J. Just was named chief of staff and **Dr. Carl A. Weiss,** secretary of the staff, at a recent meeting to name officers for the Hastings Memorial Hospital staff.

* * *

Dr. Malcolm M. Hargraves, member of the Mayo Clinic staff, known for his interest in soil conservation activities, was made an honorary member of the Soil Conservation Society of America at its national convention at Colorado Springs, Colorado, in December.

In 1948, Dr. Hargraves discovered the cell in human blood that made possible the diagnosis of lupus erythematosus.

* * *

Dr. Henry Ulrich, who helped found the Hennepin County Tuberculosis Association fifty years ago, was recently presented with a plaque in the form of the well-known emblem of the Anti-Tuberculosis Committee of the Associated Charities. The presentation was made by **Dr. S. Marx White** at a luncheon held in Dr. Ulrich's honor at the Citizens Aid Building, Minneapolis.

* * *

At a meeting of the Red River Valley Medical Society, held in Thief River Falls, November 24, **Dr. Davitt A. Felder** of University of Minnesota, spoke on "Diseases of the Blood Vessels." Following the dinner, wives of the doctors met for a short auxiliary meeting at the home of **Dr. and Mrs. William A. Feigal.**

* * *

Dr. Joseph C. Michael and **Dr. John W. Schumacher** have been associated in the practice of psychiatry and neurology at the Medical Arts building, Minneapolis, since December 1.

* * *

Dr. John G. Freeman, clinical director of the Fergus Falls State Hospital for the past two and a half years, has accepted a similar position with the State Hospital in Jamestown, North Dakota, where he will take over his new duties February, 1954.

Dr. Freeman participated as speaker at the fall meeting of the executive secretaries of the Minnesota Welfare Boards at the University of Minnesota Center for Continuation Study recently. He was also guest speaker at the American Public Welfare Association's session on "Community Planning for the Care of the Senile Patient" held in Chicago, Illinois, December 5.

* * *

Dr. Donald J. McNairy, Phoenix, Arizona, spent the week of December 7 to 11 in Chicago as a member of the teaching staff at the annual meeting of the American Academy of Dermatology and Syphilology, his subject being "Medical Photography." Dr. McNairy received his Master of Science degree in Dermatology and Syphilology at the University of Minnesota in 1944.

* * *

Dr. and Mrs. B. J. Cronwell, Jr., Austin, **Dr. Herman Miller,** Grand Meadow, and **Dr. P. J. Schneider,** Adams, met at the home of **Dr. Thomas M. Seery** in Austin, November 23, to take the first steps in organizing the Mower County Heart Council. Dr. Seery, designated acting chairman of the Minnesota Heart Association, said the object of the council will be to distribute vast amounts of educational material available through the Heart Association. The group plans a larger meeting for January in which civic and farm groups will be represented.

* * *

Dr. Moses Barron, Minneapolis, discussed developments in the Middle East at a general meeting of the Minnesota Emergency Committee on Israel of the Saint Paul Zionist district, in the Jewish Community Center, November 17.

* * *

Dr. Deane W. Benton, formerly of New Ulm, now specializing in psychiatry in Minneapolis, gave an illustrated talk on a "Laymen's View of Psychiatry" at a Rotary Club meeting held November 17 at the Silver Latch Cafe in New Ulm.

* * *

At the organization meeting of the "Catholic Physician's Guild," held in St. Cloud, November 30, with approximately thirty-five doctors in attendance, **Dr. W. T. Wenner,** St. Cloud, was elected president; **Dr. F. J. Schatz,** St. Cloud, vice president; **Dr. W. F. Skaife,** Little Falls, secretary, and **Dr. J. B. Gaida,** St. Cloud, treasurer.

* * *

Dr. Irvine McQuarrie, Professor of Pediatrics at the University of Minnesota Medical School, has been named one of tthe recipients of the 1954 Modern Medicine Award for Distinguished Achievement, Dr. Walter C. Alvarez of Minneapolis, editor-in-chief of the magazine, has announced. His contributions to the understanding of metabolic disturbance in children earned the award for Dr. McQuarrie. The awards are presented annually by *Modern Medicine* in recognition of significant work in the advancement of medical practice.

Dr. C. A. Undine, Minneapolis, attended the midwest regional meeting of the American College of Physicians at Milwaukee, Wisconsin, November 21, 1953.

* * *

Dr. G. S. Boyer, Crookston, radiologist for the Northwestern Clinic at Crookston, addressed Roseau physicians, recently, on "Infertility Studies."

* * *

Dr. John L. Delmore, Jr., Roseau, attended the orthopedics course at the Center for Continuation Study at the University of Minnesota, November 16 to 18, 1953.

* * *

Dr. A. C. Hilding, Duluth, was recently elected to membership in the Kunglia Fysiografiska I. Lund, honorary Swedish scientific organization which limits its membership to approximately 100 Swedish and 100 foreign members.

* * *

Dr. Louis L. Freidman, Saint Paul, participated in a symposium on "Surgery in Sterility" presented by the Western Division of the American Sterility Society in Palm Springs, California, November 6 to 8, 1953. Dr. Friedman also addressed the Lynn County Medical Society at Cedar Rapids, Iowa, November 12, on "Management of the Infertile Couple."

* * *

Dr. Robert S. Abernathy, Fellow in the Department of Medicine at the University Hospitals, Minneapolis, has been awarded a Research Fellowship in Medicine by the American College of Physicians. The appointment is effective July 1, 1954. He will work under the preceptorship of Dr. Wesley W. Spink, Professor of Medicine, on the pathogenesis of brucellosis. Dr. Abernathy is a graduate of Duke University School of Medicine. He interned in the University of Minnesota Hospitals, and following a year as Fellow in Medicine, he served two years in the army in Korea. Dr. Abernathy's wife, Dr. Rosalind Abernathy, is a part-time assistant in the Department of Pediatrics at the University Hospitals.

* * *

Dr. R. L. Parsons, formerly of Monterey, is now located in Glencoe, Minnesota, for the practice of medicine and surgery.

* * *

Dr. George H. Olds, New Richland, has been named a member of the Mental Health Clinic, which has its main office in Albert Lea.

* * *

Dr. E. F. Beyer, Braham, called into the army from his medical practice in May, has been promoted to the rank of captain. Dr. Beyer has been stationed with the Seventh Division in Korea since August.

* * *

Dr. Milton Moore Howell, previously in charge of a fifty-bed medical ward at the United States Public Health Hospital, Norfolk, Virginia, is now associated with **Dr. C. W. Truesdale** in the operation of the Glencoe Clinic. Dr. Howell is a graduate of the University of Rochester School of Medicine, Rochester, New York. Prior to his entering medical school, Dr. Howell was in the army from 1940 until 1945. Starting as a private he left the service a major.

* * *

Dr. George W. Snyder, Saint Paul, trustee of the American Legion's Hospital Association, pointed out at the opening session of the Minnesota fall conference, that dues allotted from membership fees are not sufficient to sustain the hospital program to be carried out by the association. This program, for wives and dependents of veterans who are financially unable to provide hospital care for their families, receives twenty-five cents of each member's dues, and five cents from each auxiliary member. Dr. Snyder urged formation of programs to raise funds for the association, especially during hospital week in February.

* * *

Dr. Raymond L. Page, St. Charles, was presented a merit award at the annual refresher course of the State General Practice Academy held at Hotel Lowry, Saint Paul, November 4. **Dr. Charles C. Cooper,** Saint Paul, is president of the group, which this year had more than 500 physicians in attendance at the sessions.

* * *

Dr. Louis Loes, who recently opened an office in St. Cloud for specialization in obstetrics, spoke at a meeting of the United Cerebral Palsy group of Central Minnesota, held in St. Cloud, December 12. He discussed problems of pre-natal care and delivery from the cerebral palsy viewpoint.

MINNESOTA BLUE CROSS-BLUE SHIELD

Of interest to all participating physicians are the improvements in both the present standard Blue Shield contract and its schedule of payments, which have been approved by the Board of Directors, for services rendered Blue Shield subscribers on and after January 1, 1954. In addition to these changes in the present standard contract, the Board expects to have a second contract with higher fees and higher service benefit annual income levels available for the public soon after March 1, 1954. The changes in the standard contract and fee schedule are the result of the Board's policy of improving the contract as rapidly as possible.

Dual Contract and Fee Schedule

A new standard contract and schedule of payments incorporating these improvements have been prepared. In the new contract will be clauses applying to the present standard contract, which will be known as Plan A, and also clauses pertaining to the new, higher fee, higher service benefit income contract, which will be known as Plan B. Principal differences in the two plans will be the fees paid and the annual incomes which determine eligibility for service benefits.

Although the new Plan B contract is not to be available to the public before March 1, 1954, in order to avoid duplication of printing and other costs, a new fee schedule containing both Plan A and Plan B fees has been prepared for early mailing to all participating physicians. Misunderstandings and other difficulties will be avoided if it is borne in mind that fees listed in the new schedule in the column headed "Fee Schedule B" do not apply to the present, or Plan A, contract.

Benefit Increases in Present Standard Contract

Service benefit annual income levels of the present contract are to be increased on January 1, 1954, from $2,000 to $2,400 for single subscribers and from $3,000 to $3,600 for family subscribers. It is believed that the increases in fees compensate physicians for providing service benefits for subscribers with these higher incomes. Prior to January 1, 1954, these annual income levels for service benefits are $2,000 and $3,000 for single and family subscribers, respectively.

When both husband and wife have a single contract, the annual income level which determines eligibility for service benefits will be the combined annual income of the family, and not the income based on the type of contract. Ambiguity has previously existed on this point. On July 1, 1953, this interpretation was approved by the Board of Directors and the contract is now being changed in this manner to clarify this ambiguity.

While the clause in the contract pertaining to in-hospital medical care limits such care, or combined medical and surgical care for the same condition, to thirty days at present, it is being changed to cover seventy days of such services rendered on and after January 1, 1954. As a result of this change, after January 1, 1954, as much as seventy days of care, instead of the present thirty days, will be provided each twelve months for every unrelated eligible condition or illness.

Waiting periods in the present group contract involving benefits for maternity care, pre-existing conditions, tonsillectomies and adenoidectomies for minor dependents, and for these and herniotomies and hemorrhoidectomies in the present non-group contract are of ten months' duration. These waiting periods are being decreased in the contract to only nine months on and after January 1, 1954. In other words, while claims for these conditions have not been eligible for payment until the subscriber has had a Blue Shield contract for ten months, claims for services rendered for these conditions on and after January 1, 1954, will be valid after the contracts are only nine months old.

Under the present contract, circumcisions are not valid claims unless the child is at least one year old. This will be changed so that circumcisions performed on and after January 1, 1954, will be eligible for payment in accordance with the fee schedule if done after the date of discharge of the mother from the hospital following the obstetrical delivery.

At present, services performed by dentists have not been valid Blue Shield Claims. Services performed by licensed dentists in Minnesota on and after January 1, 1954, in the treatment of jaw fractures, dentigerous cysts, adamantinomas, oral and extra oral drainage of alveolar abscesses will be eligible for Blue Shield allowances in accordance with the contract. Previously, such services covered by the contract were eligible for Blue Shield payment only when performed by a doctor of medicine.

Benefit Increases in the Present Schedule of Payments

In addition to the benefit improvements written into the present standard contract, an extensive revision of its fee schedule has made available more liberal allowances in surgical, medical and maternity care. In fact, of a total of ninety-five changes in the fee schedule, fifty-eight consist of fee increases, new items not listed before, or revisions of the method of payment. Most of the remaining changes represent bringing the description of the items up-to-date with present-day medical or surgical practice.

Especially important are twenty-seven distinct fee increases for different types of medical-surgical-obstetrical care. Of these, seventeen are for surgery and include $50 increases for seven difficult and more costly operations, and 10 increases in fees for recently developed and frequently performed operations. Also, six increases are for in-hospital medical care. Not only are benefits for each of the first two days of both routine and emergency in-hospital medical care being increased, but the total period of in-hospital medical care or combined in-hospital medical and surgical care for the same condition is being increased from thirty to seventy days for each period of twelve consecutive months. Maternity benefits are also being increased from $50 to $60, and three increases in anesthesia benefits are included.

Of the remaining changes, two are of particular importance to participating physicians. For treatment of sprains or strains on or after January 1, 1954, a fee of $5.00 is listed and this will permit allowances for the x-ray necessary for their diagnosis, in accordance with the contract. Also, circumcisions which have been excluded from benefits till the child is twelve months old, when performed after the date of the mother's discharge, and after January 1, 1954, will be eligible for a $10 fee till the child is three months of age, and a $15 fee from three months to six years of age. In addition to these increases, fourteen other new items are being added, and fifteen changes are being made to improve the methods of paying for foreign body removal, lacerations, burns and other surgical procedures.

No Increase of Rate for Present Standard Contract

All of these many improvements in the present contract and the schedule of payments are being made without any increase in the rate or cost of the present contract to the subscriber. These increased benefits mean several hundred thousand dollars more in benefits paid for subscribers' medical, surgical and maternity care each year. Improving the benefits without increasing the rates clearly demonstrates the Board of Directors' desire and intention of providing the greatest benefits at the lowest possible cost. This course of action is possible only with the full support and co-operation of all members of the medical profession.

BOOK REVIEWS

Books listed here become the property of the Ramsey, Hennepin and St. Louis County Medical Libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

BOOKS RECEIVED FOR REVIEW

SALT AND THE HEART. Edward T. Yorke, M.D. Attending Cardiologist, Alexian Brothers Hospital, Associate Cardiologist, St. Elizabeth Hospital, Dispensary Physician, Elizabeth General Hospital, Elizabeth, N. J.; Consultant in Medicine, Rahway Hospital, Rahway, N. J. 83 pages. Illus. Price $3.45, cloth. Linden, N. J.: Drapkin Books, 1953.

MENTAL HEALTH IMPLICATIONS IN CIVILIAN EMERGENCIES. Report of Subcommittee on Civil Defense, Community Services Committee, National Advisory Mental Health Council, May, 1953. 25 pages. Price 15c, paper cover. Washington, D. C.: U. S. Government Printing Office, 1953.

REVIEW OF PHYSIOLOGICAL CHEMISTRY. 4th Edition. Harold A. Harper, Ph.D. Professor of Biochemistry, University of San Francisco; Biochemist Consultant to Metabolic Research Facility, U. S. Naval Hospital, Oakland; Biochemist Consultant to St. Mary's Hospital, San Francisco. 328 pages. Illus. Price $4.00, paper cover. Los Altos, Calif.: Lange Medical Publications, University Medical Publishers, 1953.

A PRIMER OF CARDIOLOGY. By Geoge E. Burch, M.D., F.A.C.P., Henderson Professor of Medicine, Tulane University School of Medicine; Physician-in-Chief, Charity Hospital; Consultant in Cardiovascular Diseases, Oschner Clinic; Visiting Physician, Tuoro Infirmary, New Orleans. Second Edition. Thoroughly Revised, with 214 Illustrations, 339 pages. Cloth, $5.50. Philadelphia: Lea & Febiger, 1953.

This book is intended as a guide to the student's early clinical studies of heart disease, according to the author's preface. It is provocative and it emphasizes the use of physiological data plus logic to solve selected clinical problems. I am afraid this is not the publisher's concept of the book since he refers to it as "comprehensive in scope . . . (a) complete presentation . . . (with) emphasis on problems (of) daily practice." A modern book relating to cardiology is hardly complete if it contains not a single electrocardiogram. It is not emphasizing daily problems if it devotes fourteen pages to calculation of congenital shunts and three to angina.

The prospective buyer of the book, having in mind the author's classic monograph on electrocardiography which is similarly titled, is not likely to realize how little clinical wisdom he is purchasing. The electrocardiographic book is a primer and is practical and helpful to the practitioner. The volume being reviewed is none of these.

Even as a guide to the student the book has serious defects. For example, contrasting theories of congestive failure are presented, but the essential points of the theories are controverted in the telling. This surely is a postgraduate presentation of an interesting sort, but must be bewildering to the beginner. So much is made of physiological facts and graphs and so much stress is placed on the imperative need of more reliable data of a similar sort that the reader might not realize very notable clinical experiments have been presented in recent years directly beneficial to the science of cardiology: for example, the precise assessment of virtue in modes of treatment in infarction and the quantitative role of electrolytes in the failing heart. The medical student should be progressing steadily and rapidly to clinical considerations. Books can help, but a shiny display of mathematical formulae related to heart sounds, a forensic presentation of the author's attitudes on congestive failure (page 56), and an individualistic assessment of new techniques such as catheterization (page 219) are not likely to hasten the maturity we all yearn for.

The author's insistence on severe anemia as a sign of heart disease (meaning the latter is always present with former) and on classifying functional heart complaints as heart disease will antagonize many readers.

The pages contain some excellent discussions. The treatment of functional complaints is handled in a manner that suggests the vast clinical experience of the author. The discussion of tracheal tug in aneurism is one of the clearest the reviewer has read.

For the teacher of cardiology, even though a casual and informal one, the book should be useful. It is factual and it is an attempt at the correlation much discussed of basic science and medicine. For the student of undergraduate rank, truly physiological or clinical monographs are more suitable. For the practitioner, the book will be disappointing if not misleading. So much excellent writing has been done on heart disease it would be easy to employ the few idle hours in a busy life to better advantage.

W.B.M.

DISEASES OF WOMEN. By Robert James Crossen, A.B., M.D., F.A.C.S., Assistant Professor of Clinical Gynecology and Obstetrics, Washington University School of Medicine, Section Head of Unit Obstetrics and Gynecology, St. Louis City Hospital; Assistant Gynecologist and Obstetrician to Barnes Hospital. 10th ed. 935 pages. Illus. Price $18:50 (cloth). St. Louis: C. V. Mosby Co., 1953.

It is indicative of passing time that the new tenth edition of Diseases of Women for the first time bears the name of only one Crossen. Dr. Robert J. Crossen, as sole author, has accomplished a difficult task well. To revise a standard text, to bring it up to date and still maintain the same degree of excellence and completeness for which the original manuscript long has been known, is a monumental project. The new author, with his deletions and additions has greatly improved this already well-known book. Removing many of the pages devoted to operative gynecology, allied fields such as gastroenterology, and pathology remote from that of gynecology has not, as one would expect, made the text less complete but rather allows space for the addition of more pertinent and up-to-date data. The addition of Willard Allen's chapter of "Endocrine Control and the Ovarian Cycle," A. N. Arneson's detailed yet clear explanation of radiation therapy in cervical cancer, and the treatise on the psychosomatic aspects of gynecology from a down-to-earth viewpoint has greatly augmented the value of the book to student and practitioner alike.

Diseases of Women continues to be one of the most complete books of its kind. One seldom finds a more complete review of the anatomy, embryology, and physiology of pelvic organs even in texts devoted exclusively to those specific fields. Biochemistry and its relation to pelvic physiology is very detailed, more so than perhaps is necessary in a book of this character. The unusual section devoted to pitfalls in gynecological diagnosis alone should guarantee this edition a respected place on the shelf of the specialist as well as the general practitioner.

Perhaps this very completeness reveals itself as the only criticism the new edition demonstrates. To be used as a reference the countless paragraphs on theory of etiology, related physiology and embryology may prove to be a disquieting barricade. As a text for the student, a complete study reference for the specialist, and a thorough approach to diagnosis and treatment for the practitioner, Diseases of Women equals all and surpasses many comparable gynecological texts.

Richard R. Fliehr, M.D.

MAY'S MANUAL OF THE DISEASES OF THE EYE FOR STUDENTS AND GENERAL PRACTITIONERS. Revised and edited by Charles A. Perera, M.D., Associate Clinical Professor, College of Physicians and Surgeons, Columbia University, New York. 21st ed. 512 pages. Illus. Price $6.00. Baltimore: Williams & Wilkins Co., 1953.

The new twenty-first edition of May's Ophthalmic Manual maintains its high standing of efficiency in describing eye diseases and the latest treatments for them. The various ophthalmic operations are described and illustrated, including the newer ones for cataract, glaucoma and detachment of the retina. The book can be recommended not only for the student and practitioner, but also for the specialist.

E. R. Bray, M.D.

LIVING WITH A DISABILITY.—At Home—At Work—At Play. By Howard A. Rusk., M.D., and Eugene J. Taylor, in collaboration with Muriel Zimmerman, O.T.R., and Julia Judson, M.S. 191 pages. Illus. Price $3.50. New York: The Blakiston Co., Inc., 1953.

Dr. Rusk has had a great deal of experience with disabled people and has followed numerous cases for long periods of time. In this book he has brought out some of the means of help, which are simple in many cases and more complicated in others, but which will aid the person to be more independent. Many of the suggestions that he has, and has well pictured for physical aids, could be made in any home work shop and many of them could be varied slightly to fit the individual case.

The text of the book is interesting and easy reading, and the pictures are all largely self explanatory. It would be advisable for all doctors, and especially those who have patients with disabilities, to carefully review this book and use it as a reference for suggesting different types of aids to the handicapped.

John C. Feuling, M.D.

FLOW AND PRESSURE IN THE ARTERIAL SYSTEM, THEIR HEMODYNAMIC RELATIONSHIP, AND THE PRINCIPLES OF THEIR MEASUREMENT

ERIK WETTERER, M.D.
Munich, Bavaria, West Germany

BY THE SYSTOLIC ejection of blood into the arterial system, the heart causes a flow of fluid, the rate and course of which depend in the first rank on the diastolic filling and the momentary muscular conditions of the ventricle, and on the arterial pressure. The ejected volume extends the arteries and raises the pressure above its diastolic value. This sudden event initiates a pulse wave in the elastic arteries which is propagated through the system up to its branches where wave reflections take place. At the end of systole, the pressure is usually increased in all arteries, each of them being augmented in volume and sharing in the systolic storage of blood. The subsequent elastic recoil of the arterial walls maintains the blood flow through the capillaries during diastole.

First, the course of blood flow generated by the contraction of the ventricle, and the pressure course in the arteries near the heart, have to be considered. As an example, a selection of tracings obtained by Wetterer and Deppe [49] is seen in Figures 1 to 4. The flow rate in the unopened ascending aorta has been recorded with an electromagnetic flowmeter, the pressure in the lower carotid artery with Broemser's optical manometer,[5] and the femoral pulse with a sphygmograph. The chest of the animals was opened.

In Figure 1, the tracings of pressure and pulse taken on a rabbit show some well-known facts. In each pulse, the pressure rises suddenly, reaches its maximum near the middle of systole, and then decreases towards the end of systole where the incisura appears. During diastole, the pressure is generally falling, but, due to a superimposed wave, there is an elevation in the first half of diastole, synchronous with a deep depression of the peripheral pulse. In this way, the standing wave in the aorta makes its appearance. The flow rate rises suddenly, too, reaches its maximum before the maximum of pressure, then turns back to zero and becomes negative for a very short time at the end of systole during the closure of the aortic valves. During diastole, the flow remains practically at zero.

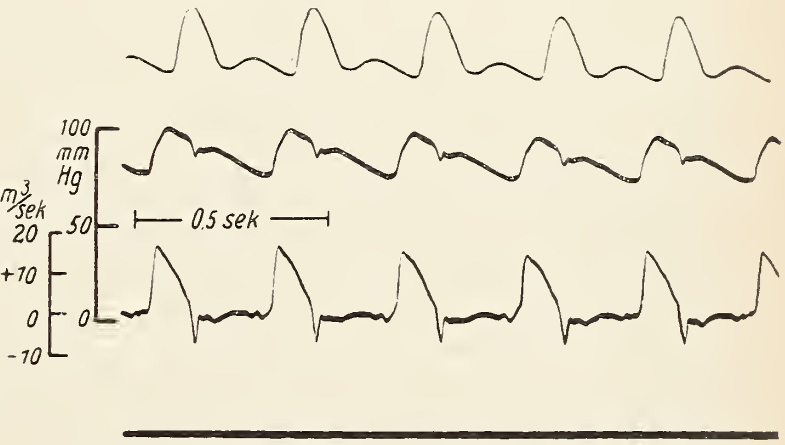

Fig. 1. Records taken on a rabbit. Tracings from bottom to top: flow rate in the ascending aorta, pressure in the carotid, femoral pulse.

A large stroke volume was obtained by adrenaline, as demonstrated in Figure 2. In this special case, the flow course is characterized by a plateau or two maxima, respectively. This is a very

---

Presented in the Symposium on Recent Advances in Cardiovascular Physiology and Surgery, University of Minnesota, Minneapolis, September 15, 1953.

unique phenomenon which was observed in no other animal. In consequence of the high peripheral resistance and the increased pulse wave velocity, the course of pressure is remarkably elevated in the last part of systole by a large reflected wave, the onset of which is clearly seen. The relatively small pressure fall after the systolic maximum and the curved descent of pressure during the prolonged diastole are obvious.

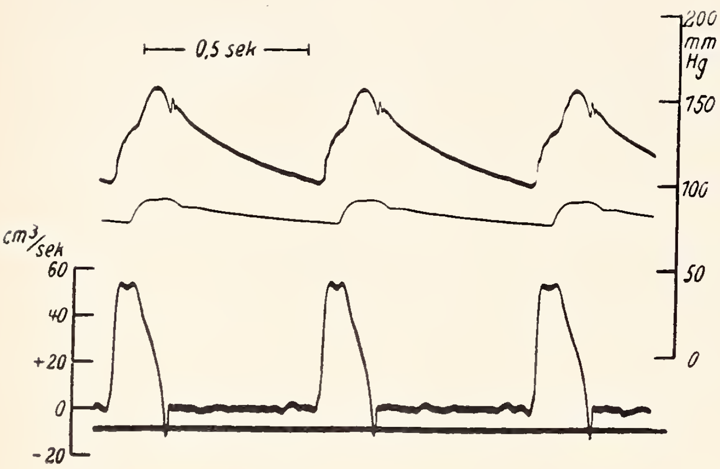

Fig. 2. Records taken on a rabbit after injection of adrenaline. Tracings from bottom to top: flow rate in the ascending aorta, femoral pulse, pressure in the carotid.

An opposite state of circulation is seen in Figure 3 after the injection of pilocarpine. The peripheral resistance and the mean pressure are low, and the pulse wave velocity is slow. At the end of systole, there is only a minute negativity of flow and, therefore no visible incisura in the pressure curve. After the relatively deep descent from the systolic pressure maximum to the end of systole, the diastolic pressure course is almost horizontal. The time interval between the maxima of flow and pressure is very short. In this case of low pressure level, the courses of pressure and flow are nearly congruent, if presented on the same scale.

Figure 4 shows a record obtained on a dog of 15 kgm. The maximum of flow rate approaches 200 cc. per sec. Attention is to be called to the fact that there are no significant differences in shape of the normal flow course between rabbits, cats, dogs, and monkeys. It may be concluded that the contour of flow course in the human ascending aorta agrees in the principle with those which have been recorded on these animals.

Obviously, the integral of the flow rate (that is the area enclosed by the curve of the flow rate and by the base line of flow) represents the total stroke volume minus that minute part flowing through the coronary arteries during systole. The cardiac ejection curve (that is the time course of volume ejected by the ventricle) results from the stepwise integration of the flow curve from the beginning to the end of ejection time. Some ejection curves, obtained in this way, are seen in Figure 5. Above, the original curves of flow rate. The ejection curves are S-shaped. Generally, the steepest point which corresponds to the maximum of flow rate is situated within the first fourth or third of the ejection time. On the right hand of Figure 5, there is an ejection curve calculated by Remington and Hamilton[40] with their pulse contour method. On the whole, the differential quotient of this calculated ejection curve agrees well with the recorded flow curves although the maximum of the recorded flow course is usually reached somewhat earlier than that of the calculated curve.

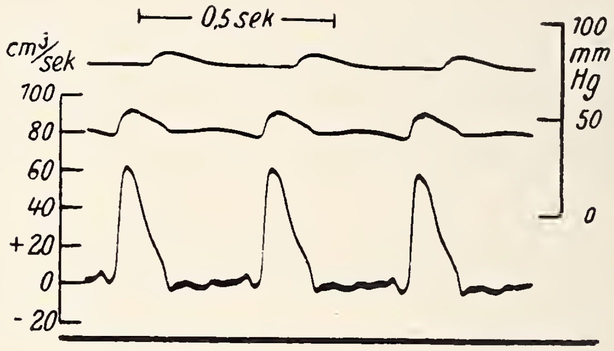

Fig. 3. Records taken on a rabbit after injection of pilocarpine. Tracings as in Figure 1.

Because of the intricate structure of the arterial system, the theoretical treatment of the hemodynamic events is faced with many difficulties. Therefore, several authors tried to formulate the fundamental laws concerning pressure and flow by the study of simplified models. Two different models have proved valuable: the so-called Windkessel and on the other hand, a long elastic tube filled with fluid through which pulsewaves are propagated. The Windkessel model, as shown in Figure 6, consists of a distensible reservoir, representing the distensibility of the total arterial system, an inflow valve representing the aortic valves, and a narrow outlet tube representing the peripheral resistance. Instead of the distensible reservoir, an air-filled rigid box can be used; hence the name air-chamber or Windkessel. If fluid is injected rhythmically by means of a pump, imitating systole and diastole of the heart, the pressure in the Windkessel rises and decreases rhythmically. In 1899, Frank[10] described the relation between rate of inflow i and pressure p by the equation noted in Figure 6 at the right hand. D is the distensibility, that is the ratio of a change in volume to a change in pressure, and R is the resistance. It is seen that the inflow rate is resolved into storage rate i_1 and an outflow rate i_2. i_1 distends the elastic wall and results in an uptake of fluid, while i_2 represents the drainage out of the system.

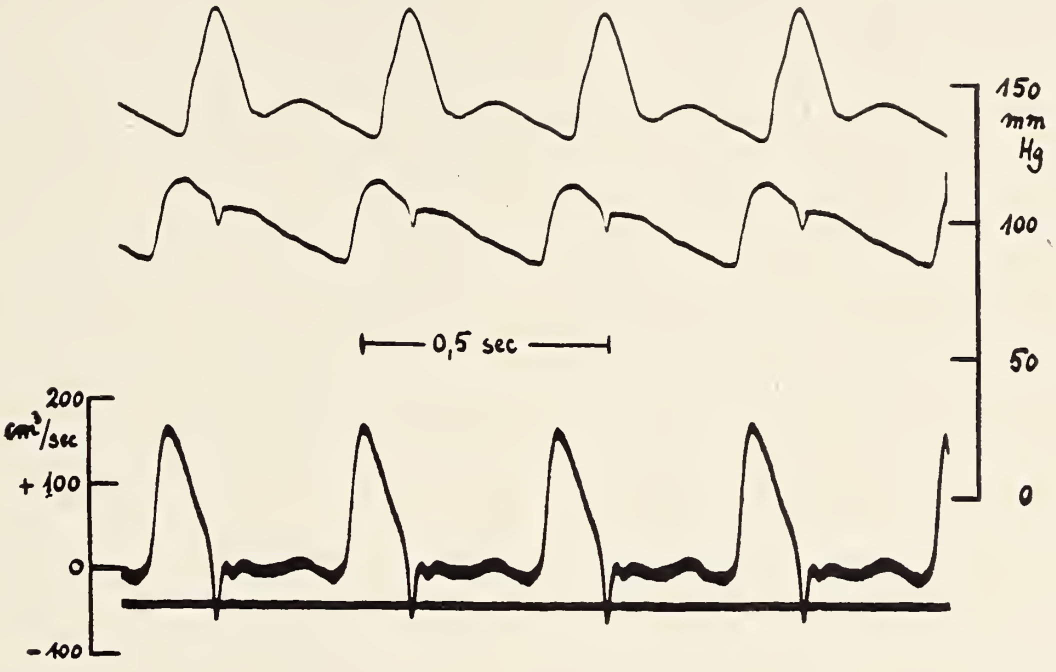

Fig. 4. Records taken on a dog of 15 kgm. Tracings as in Figure 1.

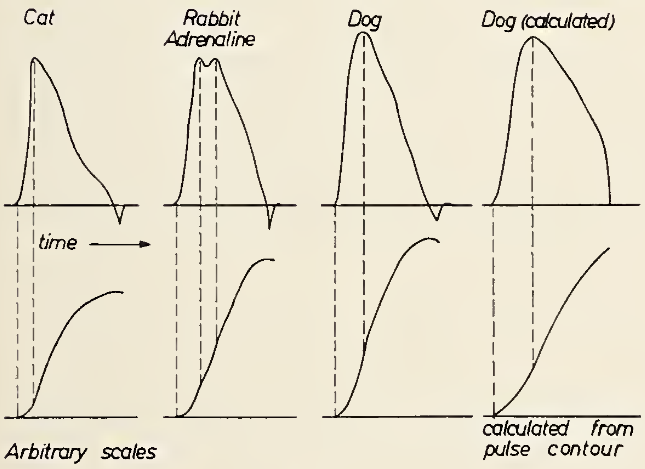

Fig. 5. First, second, and third curve from left to right: Derivation of the cardiac ejection curve (below) from the recorded course of flow rate in the ascending aorta. Last curve at the right hand: Ejection curve (below), calculated by Remington and Hamilton from the pulse contour, and its differential quotient (above).

The pressure course in the Windkessel results from the integration of Frank's differential equation under the assumption of a certain flow course. Thus, a slowly ascending S-shaped pressure course results during systole. The diastolic pressure descent describes, as Frank stated, an exponential curve, if the product resistance times distensibility is constant during diastole. In the limits of a normal diastole, the curvature of the diastolic pressure course is only slight so that it approaches a straight line.

$D = \frac{dV}{dp} = \frac{1}{E'}$

Fig. 6. Design of the simple Windkessel model.

Wetterer[50] emphasized that the systolic pressure course in the Windkessel is quite different from that in the normal arterial system. Nevertheless, the following time correlations between flow and pressure during systole are valid for both the Windkessel and the arteries: the maximum of flow precedes the maximum of pressure; the maximum of pressure precedes the maximum of ejected volume. These relations hold true with regard to the total arterial system as well as to its single branches.

The Windkessel model also permits the prediction of the effects of changes in stroke volume or minute volume, in distensibility or resistance on the mean pressure level and on the pulse pressure. In this regard, Wiggers[61] investigated similar physical models in an experimental way in 1938.

It was mentioned above that the Windkessel model is unable to deliver a systolic pressure course analogous to that of the normal arterial system. However, an extremely high peripheral resistance can give rise to an arterial pressure contour similar to that in the Windkessel, for instance, in cases of renal hypertension as recently published by Remington.[41] But usually, the arterial pressure during systole ascends much steeper, reaches its maximum earlier and decreases, after the maximum, to a greater extent than the pressure in the Windkessel does. In 1940, Wetterer[50] tried to explain these differences between the model and the natural circulation system by the following consideration: In all parts of the Windkessel reservoir the pressure is the same at a certain moment so that the total distensibility is effective during the entire pulse time. But in the arterial system, the distensibility is variable and depends on the distance covered by the pulse wave. In the beginning of the systolic inflow, the pulse wave starts from the aortic root. For instance, 10 milliseconds after, the top of the wave will have passed through about four centimeters. Only the distensibility of this short part of the aorta will be available for the uptake of blood injected during the first 10 milliseconds. The longer the distance covered by the pulse wave, the greater will be this part of the arterial system in which uptake occurs. Consequently, the actual distensibility during systole is variable and a function of time. Wetterer calculated this variable distensibility from the pulse wave velocity and the cross sectional area of the aorta under certain simplified assumptions. Furthermore, he supposed the drainage rate obeying two different laws: first, the simple law of Poiseuille, and second, another relation resulting from the consideration that the drainage rate increases with the number of arterioles reached by the pulse wave. In this way, the flow course was calculated from the pressure course and inversely, and in many cases a satisfactory correspondence between the calculated and the recorded curves was obtained. On the other hand, this calculation was failing in cases of a very high or very low peripheral resistance. Therefore, it may be stated that this extension of the simple Windkessel theory improves our classical model to a certain degree, but cannot take into account all variations occurring in circulation.

Independently of these considerations, Hamilton and Remington[21] developed in 1946 and 1947 a new method of calculating the cardiac ejection curve from the pressure course. The distensibility used in their calculations was not derived from the pulse wave velocity, but from volume pressure relations directly determined on dead animals. The arterial system was divided into six main beds, the individual volume uptakes of which were tabulated at different pressure levels. Also the pulse transmission time to and through each bed was listed at various pressures. Using these statements, the authors computed the time course of the volume uptake from the pulse pressure recorded on living animals. Obviously, the contribution of the separate beds to the momentary uptake varies considerably in the course of systole according to the distance covered by the pulse wave, and the variation of the actual distensibility as a function of time, is a striking feature of this method too. Furthermore, Hamilton and Remington described the systolic drainage of blood as a complex function of the distance covered by the pulse wave and of the arterial pressure. The total ejection curve, resulting from uptake plus drainage, was found to be an S-shaped curve as demonstrated in Figure 5 and also confirmed by cardiometer curves of Wiggers and Katz.[59]

The percental contribution of the various arterial beds to the total distensibility, as it may be quoted from the tables of Hamilton and Remington, is very different. The entire aorta comprises at the most 50 per cent of the total distensibility, the arteries of head, neck, and forelegs nearly 30 per cent, the visceral plus hindlimb arteries about 20 per cent. Of course, also the smallest arteries of each bed contribute to the distensibility.

Wetterer and Pieper[54] developed in 1952, a direct method for determining the total arterial distensibility on living anesthetized animals. A piston pump filled with Ringer solution was connected to the aorta by a tube introduced through the carotid. The piston moved forward and backward and effected rhythmic sinusoidal volume changes; each pump cycle lasted three to five seconds. The volume shift of the piston was adjusted to the size of the experimental animal. In dogs of 8 to 30 kgm. volume changes of 10 to 30 cc. were used. The blood pressure in the aortic arch, recorded with a miniature manometer,[52,53] increased and decreased with the rhythm of the pump motion. On these relatively slow fluctuations, the arterial pulses were superimposed, as shown in Figure 7. The pulse transmission time through the whole arterial system is exceedingly short compared to the duration of a pump cycle. Therefore, the arterial system reacts to the pump like the uniform reservoir of a simple Windkessel model. For evaluation, the measurements were carried out on the diastolic parts of the pulses. Within a pump cycle of the aortic pressure course, two pulses were selected, one in the ascending part and the other one in the descending part. The mean pressures during the diastoles of both pulses should not differ from each other by more than 2 per cent so that the mean diastolic drainage rates may be supposed to be equal. The distensibility of the total arterial system was given by the formula:

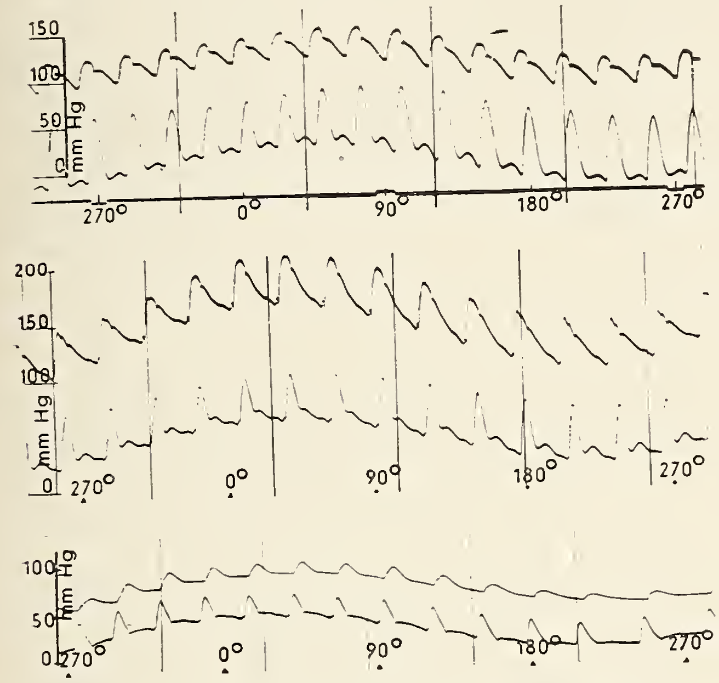

Fig. 7. Tracings obtained on anesthetized dogs during the action of the pump (see text). Above: normal state; aortic pressure and femoral pulse. Middle: high pressure during infusion of adrenaline after atropinisation; aortic pressure and femoral pulse. Below: low pressure due to a ganglionic blocking drug (Pendiomid); femoral pulse and aortic pressure.—Distances between the vertical lines = 1 sec.—Numbers below zero-line indicate the angle-degrees corresponding to the sinusoidal movement of the piston. 270° = lowest position, 90° = highest position of the piston.

$$D = \frac{i_1 - i_2}{S_1 - S_2}.$$

i_1 and i_2 are the flow rates of the pump during the diastoles of the two pulses, calculated by means of a sine table. S_1 and S_2 are the diastolic pressure slopes of the two pulses. The drainage cancels out in this formula because it is the same for both pulses. The evaluation of ten to twenty pairs of pulses in every record containing several pump cycles gave a standard deviation of about 8 per cent and a mean standard error of less than 3 per cent.

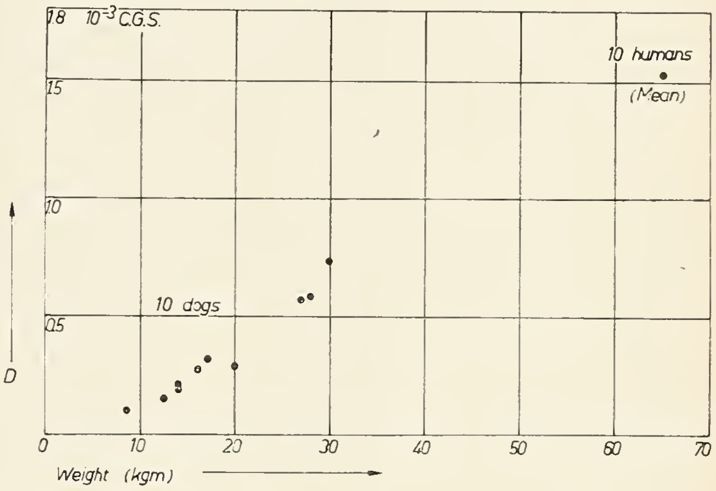

Fig. 8. Total arterial distensibility of ten anesthetized dogs, determined with the pump method. Above at the right hand: Mean of arterial distensibility, determined on ten humans by Warner *et al.*

Figure 8 shows a summarizing diagram of the results obtained on ten dogs of body weights between 8.5 and 30 kgm. in a normal state of circulation. The distensibility, expressed in C.G.S. units, is plotted against the body weight in kgm. The relation between both variables may be regarded as a curve passing through the origin of the co-ordinates and becoming steeper in the range of greater body weights. As far as it can be seen from ten observations, the distensibility is not highly influenced by differences in age and sex of the dogs. The amount of distensibility measured on dogs of 28 to 30 kgm. agrees well with the data calculated from the tables of Hamilton and Remington[21] under the condition of a normal pressure level. Moreover, the results obtained on dogs with the pump method may be substantiated by the investigations of Warner, Swan, Connolly, Tompkins, and Wood[36] who computed on humans, the arterial distensibility from the aortic pressure pulse and from the cardiac output determined by Fick's principle of the dye method. The mean of distensibility determined on ten normal humans and expressed in C.G.S. units is noted in Figure 8 under the assumption of a mean body weight of 65 kgm. Obviously, an extrapolation of the values measured on dogs points almost directly to the mean of human arterial distensibility.

If the distensibility of the entire human arterial system should be simulated by an air-chamber model, an air-cushion of 1.5 to 2 litres would be required.

Now, the arterial pressure course during diastole may be discussed. It was explained above that in diastole the descending pressure in the simple Windkessel follows an exponential course which represents almost a straight line. In the arterial system, the diastolic pressure course resembles a straight line, too, if the diastole is not abnormally long, and if pressure changes induced by wave reflections do not interfere. At a certain pressure level, the slope of this course is reciprocal to the product distensibility times peripheral resistance. An undisturbed diastolic pressure course may be obtained at the node of the main standing wave in the aorta.

If, in an abnormally prolonged diastole, the pressure falls over a wide range, we find a diastolic pressure course which follows a strongly curved line. Extrapolating this curve beyond the end of diastole, one does not reach values which correspond to the capillary or venous pressure. Rather the extrapolated curve seems to be asymptotic at a level which is far above the capillary pressure. Several reasons explain this fact: First, the arterial distensibility is a function of pressure; it increases when the pressure decreases. Second, the peripheral resistance, too, is a function of pressure because the lumen of the arterioles decreases with falling pressure. Both phenomena result in a rise of the product distensibility times resistance. Hence, the pressure course is flattened. Furthermore, in arterioles and capillaries the relation between pressure and flow of blood does not obey Poiseuille's law because blood deviates from the properties of a homogeneous viscous fluid in narrow vessels. As to the diastolic pressure course, see the publications of Frank,[12] Wiggers,[62] Hamilton,[24] Gomez,[17] and Deppe.[8] The complex relationship between pressure and flow through the arterioles and capillaries has been studied chiefly by Hess,[23] Whittacker and Winton,[58] A. Müller,[32,33] Green and co-workers,[18] Pappenheimer and Maes,[34] Lamport,[28] Rashewsky,[38] and recently by Wezler.[56,57]

In the following, the arterial pulse waves shall be discussed. The theory of waves running through elastic tubes has been founded by the brothers Weber,[47] by Moens,[31] Korteweg, and others during the nineteenth century. Several authors contributed to its further improvement in the twentieth century, chiefly Frank[14] since 1920. Also Apéria,[2] in collaboration with a mathematician, Müntz, and recently Lambossy[27] were working on the wave theory. Landes[29] demonstrated that the fundamental hydromechanical wave equations are analogous to those which are valid for the transmission of electric impulses through telegraph-cables. The mathematical wave theory cannot be given here; the explanations may be restricted to some simplified considerations.

If a certain amount of fluid is pumped quickly into an elastic tube containing fluid, the whole column in the tube resists to a sudden dislocation due to its inertia. First of all, the wall of the initial part of the tube is distended by the injected volume. Then the elastic force of the extended wall causes a shift of fluid to the next segment, and so on. Therefore, the extension is propagated along the tube and is accompanied by a pressure rise and a movement of fluid from one segment to the next one. If there is no wave reflection, the courses of wave-pressure and wave-flow will be in phase. This is very important for the understanding of the contour of certain pressure pulses. The ratio of pressure to flow rate of the wave is a sort of impedance and may be called the wave-resistance R_w:

$$R_w = \frac{\delta . c}{A}.$$

δ is the density of the fluid, c the wave velocity, and A the cross sectional area of the tube. Friction and viscosity are not considered in this formula. Another formula developed by Frank[14] in 1920, and by Bramwell and Hill[4] in 1922, shows the direct relation between the wave velocity, the density and the so-called volume elasticity modulus α. The latter represents the reciprocal of the distensibility per unit volume.

$$\alpha = \delta c^2.$$

If the tube wall effects a viscous resistance besides its elasticity, the volume elasticity modulus and the pulse wave velocity depend to a certain extent on the quickness of stretching. Concerning the arteries, Ranke[37] investigated this phenomenon in a theoretical and experimental way. It gives rise to effects of hysteresis, particularly in the first part of systole.

The formula of Frank and of Bramwell and Hill has been used, and also discussed by many investigators, because it renders the possibility to calculate the arterial distensibility from the pulse wave velocity. The application of this formula postulates the measurement not only of the wave velocity, but also that of the total tube volume V or its equivalent:

$$D = \frac{V}{\alpha} = \frac{V}{\delta c^2}$$

The measurement of V is difficult in the case of arteries *in situ* because the arterial diameter is not the same in all sections and depends on the pressure and on the vasomotor tone of the muscular vessels.

In order to obtain an equivalent of volume V, Frank and his associates multiplied the cross sectional area of the ascending aorta by a certain length. Broemser and Ranke[6] supposed that this length was represented by the distance covered by the pulse wave during the ejection time. Frank[15] used the half of the wave length of the main standing wave, Wezler and Böger[55] only one-fourth of this wave length. Bazett and co-workers[3] tried to improve the method by a more detailed consideration of central and peripheral arteries. On the average and under normal circulatory conditions, the values of distensibility, obtained on dogs by Frank's calculation, agree with those determined by the pump method of Wetterer and Pieper[54] which has been described above. The values calculated with the method of Broemser and Ranke are similar or somewhat larger; those of Wezler and Böger are smaller than Frank's data. The calculations of the arterial distensibility from the pulse wave velocity were used for the estimation of the stroke volume in different ways, the validity of which has been examined by many comparison experiments. In numerous cases a satisfactory agreement with the results of the comparison methods was observed; in other cases, the formulas gave remarkable deviations. This is not surprising because, up to now, there is no hemodynamic calculation which respects all the variable properties of the arterial system. Not only the calculation of the arterial distensibility from the wave velocity involves certain difficulties, but also the determination of the ratio of systolic to diastolic drainage may imply some errors, particularly in cases of high pulse pressures and a high arteriolar vasomotor tone.

The pulse contour method of Hamilton and Remington[21] is based on more experimental data than on indirect calculations. Its fundamental conception consists chiefly in the direct and detailed measurement of the arterial distensibility and in the consideration of the pressure distribution in the arteries at the end of systole. About the latest development and the range of applicability of this method see the paper of Dr. Remington in this volume.

Reflections of tube waves occur when the wave resistance, that is the quotient c/A, is changing from one tube segment to another. Generally, this quotient increases from the heart to the periphery so that we conclude that wave reflections take place within the whole arterial system, especially in the arms and legs. Since the increase in wave resistance is highest in the terminal arteries, the major part of all reflections must occur here. It is obvious that the vasomotor state of these vessels determines the amplitudes of the reflected waves.

In his interesting conception, Remington[41] presented the arterial system as to be fused into a single funnel-shaped tube. The length co-ordinate of this figure corresponds to the pulse transmission time, and its local diameter to the distensibility per unit transmission time. It can be demonstrated by a simple calculation that this diameter is inversely proportional to the wave-resistance.

Reflected waves running to the aortic root are reflected anew. The interference of the primary pulse wave with reflected waves, or of reflected waves with one another, gives rise to standing waves which have been described first by Frank.[12,15] The main standing wave, thoroughly investigated by Hamilton and Dow,[20] is generated between the heart and the leg arteries. It is characterized by periodical damped undulations which are superimposed on the fundamental pressure contour. In the arteries near the heart, the phase of these undulations is opposite to that in the lower aorta and its branches. Between both regions of opposite phase we find a node which is situated in the thoracic or upper abdominal aorta. The main standing wave comprises half a wave length,[15] or, in other words, the natural period of the standing wave is twice the pulse transmission time from the heart to the peripheral end of the standing wave. Furthermore, the pulse transmission time from the heart to the node equals that from the node to the peripheral end.[42] In man, the node is usually situated in the upper abdominal aorta[42,24] and can be shifted towards the heart by compression of the leg arteries below or above the knees.[25]

Recently Alexander[1] assumed the standing wave in the aorta to be influenced by a negative wave reflection at the level of the diaphragm where large arteries are branching off from the aorta.

The pressure amplitudes of reflected waves increase if the peripheral resistance is raised, whereas the reflections can be minimized by an extreme vasodilation. The shape of the central pressure pulse is highly influenced, not only by the cardiac ejection course and the drainage, but also by reflected waves, as shown in the Figures 1 to 4. In the state of an increased peripheral resistance and a high pressure level, the pressure will not descend in the second half of systole, but remain at a plateau or even arise to a late maximum because of the superposition of reflected waves. On the other hand, a low peripheral resistance effects a pressure fall from the early systolic peak to the incisura so that the systolic pressure course is similar to the flow course in the ascending aorta. In case of the first extreme, the arterial system approaches the simple Windkessel because the high pulse wave velocity and the multiple and pronounced reflected waves effect an almost uniform filling. The second extreme, however, is characterized by insignificant wave reflections so that the arterial system approaches the simple long tube model in which the course of pressure corresponds to the course of flow. It is seen that the properties of the normal arterial system are intermediate between both extremes and that a combination of the Windkessel and the wave theory is required for the complete understanding of hemodynamics.

The pressure contour in peripheral arteries, for instance in the leg arteries, is generally characterized by a steep and long systolic upstroke, by an increased pulse pressure, and by one or two distinct diastolic undulations, called dicrotic waves, which are related to the standing waves. The shape of upstroke is chiefly caused by the facts that the peak of the pulse wave is propagated more quickly than the foot, and that steady wave reflections raise the pulse pressure. However, the mean pressure is almost the same in all large and middle arteries, provided that the body is in a horizontal position. The main pressure drop takes place in the arterioles.

Within the limits of this brief survey, it is not possible to describe all the details of the pressure course and their changes along the arterial system which have been investigated by many authors, chiefly by Frank and his associates, by Wiggers, by Hamilton, and recently by Laszt and Müller.[30] The so-called water hammer pulse has been analyzed by Alexander[1] and by Peterson.[35] Further particulars concerning pressure and flow may be mentioned in the following methodical notes:

The principles of modern membrane manometers, established by Frank[11] since 1903, are well known. The natural frequency depends on the volume elasticity coefficient of the membrane and on the effective mass of the fluid in the connecting tubes. Well approved optical manometers have been designed by Frank,[13] Broemser,[5] Wiggers,[60] Hamilton.[19] Electrical manometers are advantageous in several respects. Their sensitivity can be adjusted over a wide range only by change in amplification, and the manometers may be operated independently of the distance from the recording camera. The deformations of the membrane can be transduced into electrical magnitudes by changing the electric resistance of a stretched wire, by changing the capacitance of a condensor or the inductance of an electric choke. Also the variable coupling of the two sections of a differential-transformer may be used. Another way of transducing mechanic into electric magnitudes consists in the photo-electric effect. Furthermore, special electronic tubes have been developed in which an internal electrode can be shifted from outside by the manometer membrane.

Special technical problems arose by the cardiac catheterization first performed on man by Forsmann and worked out for clinical use by Cournand.[7] A long and narrow catheter attached to the manometer lowers the natural frequency of the recording system. Furthermore, the catheter becomes distensible if warmed up to body temperature. A suitable damping ratio is required if distortions of the tracings shall be avoided. Hansen[22] published a theoretical treatise about these problems. After Wood,[63] the artefracts caused by impacts on the catheter in the beating heart may be reduced sufficiently by a damping ratio which gives the manometer system a uniform dynamic response up to 10 cycles per second and a sharp cutoff in sensitivity above this range. A manometer adjusted in this way is able to record the practically important components of the human pressure pluse; but, of course, the particulars of higher frequencies will not be reproduced.

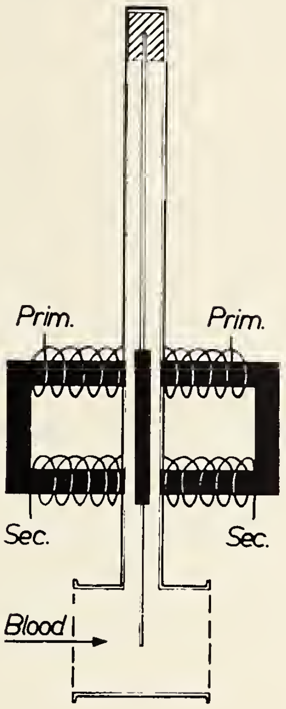

Fig. 9. Sketch of the hydrometric pendulum developed by Pieper and Wetterer. The short horizontal tube is inserted into a blood vessel. The pendulum itself is suspended elastically in the side tube and carries a small slug of iron which, in case of deflection, changes the mutual inductance of the differential-transformer. The natural frequency of the pendulum is more than 200 cps.

A natural frequency of 500 to 1,000 cps, and an artefact-free performance are obtained by miniature manometers attached to the tip of a cardiac catheter. Former devices have been published by Schütz[43] and by Wagner.[45] Wetterer[52] adopted the principle of recording small displacements with the help of differential-transformers for the construction of a miniature manometer with a high natural frequency. This instrument has been improved and adapted for use in humans by Gauer and Gienapp.[16] Ellis, Gauer, and Wood[9] examined its properties in comparison with a strain gauge type.

The measurement of blood flow involves greater difficulties than that of pressure. The mean rate of flow may be measured by instruments called "Stromuhren." Some of them are based on the principle of Ludwig's Stromuhr or on Shipley's[44] rotameter type, and are inserted into an opened vessel while Rein's Thermostromuhr[39] is applicable to unopened vessels. Another sort of flowmeters is able to record the pulsatile flow with all its instantaneous variations. This kind, based on hydromechanic or electric principles, may be called "tachographs." The hydromechanical devices are founded on friction and inertia of the moving blood. For instance, a pressure drop is effected when the blood is led in a Venturi-tube from a wide to a narrow segment. This pressure drop, recorded with a differential-manometer, equals the sum of a term proportional to the blood velocity and another term proportional to the square of velocity. A similar effect is obtained by the Pitot-tubes and their variations. The so-called hydrometric pendulum consists of a minute lever which is suspended elastically in a right angle to the direction of blood flow, and is deflected by the moving blood. In the electromagnetic flowmeter [Kolin 1936;[26] Wetterer 1937[48]], the blood moves through a magnetic field so that potential difference is induced which is proportional to the blood velocity. The application of an alternating magnetic field, introduced by Kolin, has added considerably to the further improvement of this method.

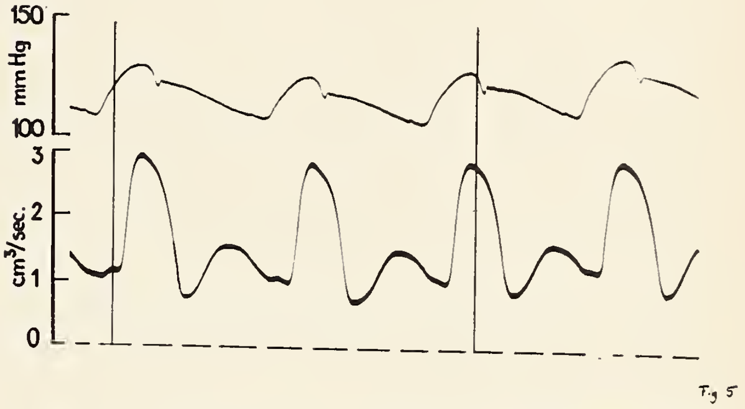

Fig. 10. Course of flow rate in the femoral artery of a dog, recorded with the device of Fig. 9. Above the pressure course in the aortic arch.

Finally, an improved model of the hydrometric pendulum, recently developed by Pieper and Wetterer,[36] may be demonstrated. The deflections of the pendulum are transduced into electrical magnitudes by means of a special differential-transformer as shown in Figure 9.

The course of flow rate in the femoral artery of a dog, recorded with this device, is seen in Figure 10. There is a relatively high diastolic flow rate and a diastolic flow wave which is related to the standing wave.

Figure 11 shows the normal flow course in the carotid. It contains the incisura, coincident with a decline between two maxima. The maximum of carotid flow precedes the maximum of pressure in the aortic arch. The diastolic undulations of flow are probably caused by pressure undulations of the main standing wave. But these undulations of flow are much more pronounced than those of pressure. Towards the end of diastole, the flow rate decreases almost corresponding to the diastolic pressure descent.

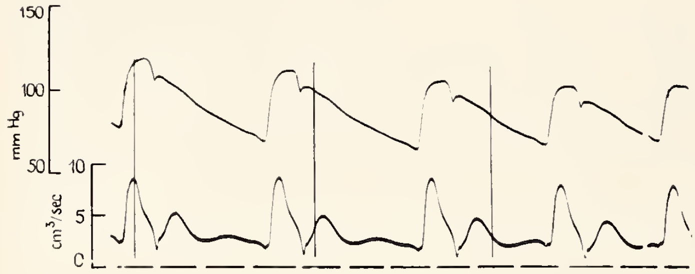

Fig. 11. Normal flow course in the carotid of a dog, recorded with the device of Fig. 9. Above the pressure course in the aortic arch.

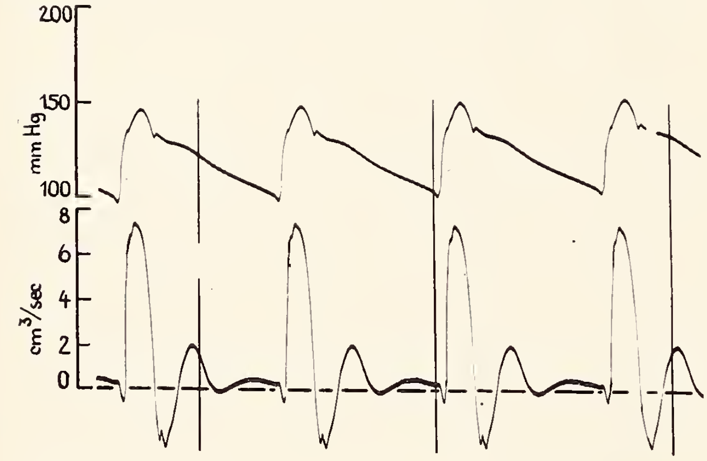

Fig. 12. Caritod flow course after injection of adrenaline. Above the pressure in the aortic arch.

The effect of a moderate dose of adrenaline is seen in Figure 12. In contradistinction to the previous figure, the mean diastolic flow rate is very low. It must be concluded that, under the condition of an increased peripheral resistance, the main portion of drainage takes place during systole; for the high pressure during systole has a much stronger opening effect upon the constricted arterioles than the lower pressure during diastole.

In the present state of hemodynamics, we are not able to explain all the details concerning the relations between pressure and flow in a quantitative way. But we hope that by improvement of flowmeters we will be able to record pressure and flow simultaneously in many parts of the arterial system in order to obtain better understanding of their interrelationship.

MEASUREMENT OF PRESSURES BY CARDIAC CATHETERS IN MAN

EARL H. WOOD, M.D., Ph.D., ISIDOOR R. LEUSEN, M.D., HOMER R. WARNER, M.D.,
and J. LEO WRIGHT, M.D.
Rochester, Minnesota

THE RECORDING of pressures from the chambers and vessels of the right side of heart in man must usually be done by means of a cardiac catheter connected to a manometer. The dynamic response of such a system can quite easily be made adequate for sufficiently accurate reproduction for most purposes of the pressure pulses in question.[1,5,8] However, serious pressure artifacts, caused by impacts on and motion of the catheter imparted by the heart beat, practically preclude high fidelity pressure pulse recording by this method if conventional catheter-manometer systems are used.[1,4] This study was carried out to obtain data concerning the optimal dynamic response characteristics of cardiac catheter-manometer systems for recording of pressure pulses by venous catheterization in man.

Methods

Pressure pulses, and other physiologic variables were recorded during routine diagnostic cardiac-catheterization procedures,[7] by a photo-oscillographic assembly described elsewhere.[6] In the majority of the experiments, pressures were recorded via the catheter by means of a specially adapted strain gauge manometer.[7] The over-all dynamic response of this catheter-manometer system could be varied instantaneously by a multipole switch, connected so as to allow recording of the pressure pulses interchangeably by three different galvanometers with natural frequencies of 5, 12, and 25 cycles per second, respectively. In part of the experiments the catheter pressures were recorded interchangeably, by turning a stopcock either by a high-frequency capacitance manometer,* or the strain gauge manometer. The resonant frequency and damping characteristics of the catheter-manometer assemblies used were determined at the conclusion of each catheterization procedure by recording the responses of the systems to square wave and variable frequency sine wave pressure variations generated by an electromagnetic hydraulic pressure oscillator described elsewhere.[3,6] Care was taken that the conditions of fluid filling and hydraulic connections between catheter and manometer were identical to the conditions pertaining during the experiment.

The susceptibility of the catheter-manometer systems to pressure artifacts, caused by motion of the catheter, was also studied at the termination of each procedure soon after withdrawal of the catheter tip from the vein. The apparatus used consists of a motor-driven cam, which imparts either a sine wave or a square wave motion to a shaft, to which the tip or shaft of the catheter can be clamped. The sine wave motions were at a frequency of 2 per second and peak-to-peak amplitude of 2 cm. The frequency of the square wave impacts was 1 per second. The pressure artifacts, generated when the catheter was subjected to these motions along the axis of the tip and perpendicular to the tip or the midshaft of the catheter, were studied.

Results

Studies of this type have been carried out during thirty catheterization procedures using strain gauge manometer systems only, and in seventeen procedures using the strain gauge and capacitance manometers interchangeably. The catheters used were of the Cournand type, either 100 or 120 cm. in length, and varying in diameter from size 4 to 7 French.

In general, the dynamic response characteristics of catheters of a given size and length, connected to the strain gauge manometer, were quite closely reproducible from procedure to procedure. This reproducibility was not obtained with the higher frequency capacitance manometer system, in spite of extreme care in attempting to insure minimal compliance of hydraulic connections, and

avoidance of entrapment of minute air bubbles.

Catheter-manometer systems with low dynamic response characteristics uniformly produced pressure pulse recordings with less evident distortion by motion artifact than did the higher frequency systems. This difference was especially evident for pressure recordings taken when the catheter was threaded through the beating heart, as is the case for pulmonary-artery wedge, pulmonary arteries and right ventricle pressures.

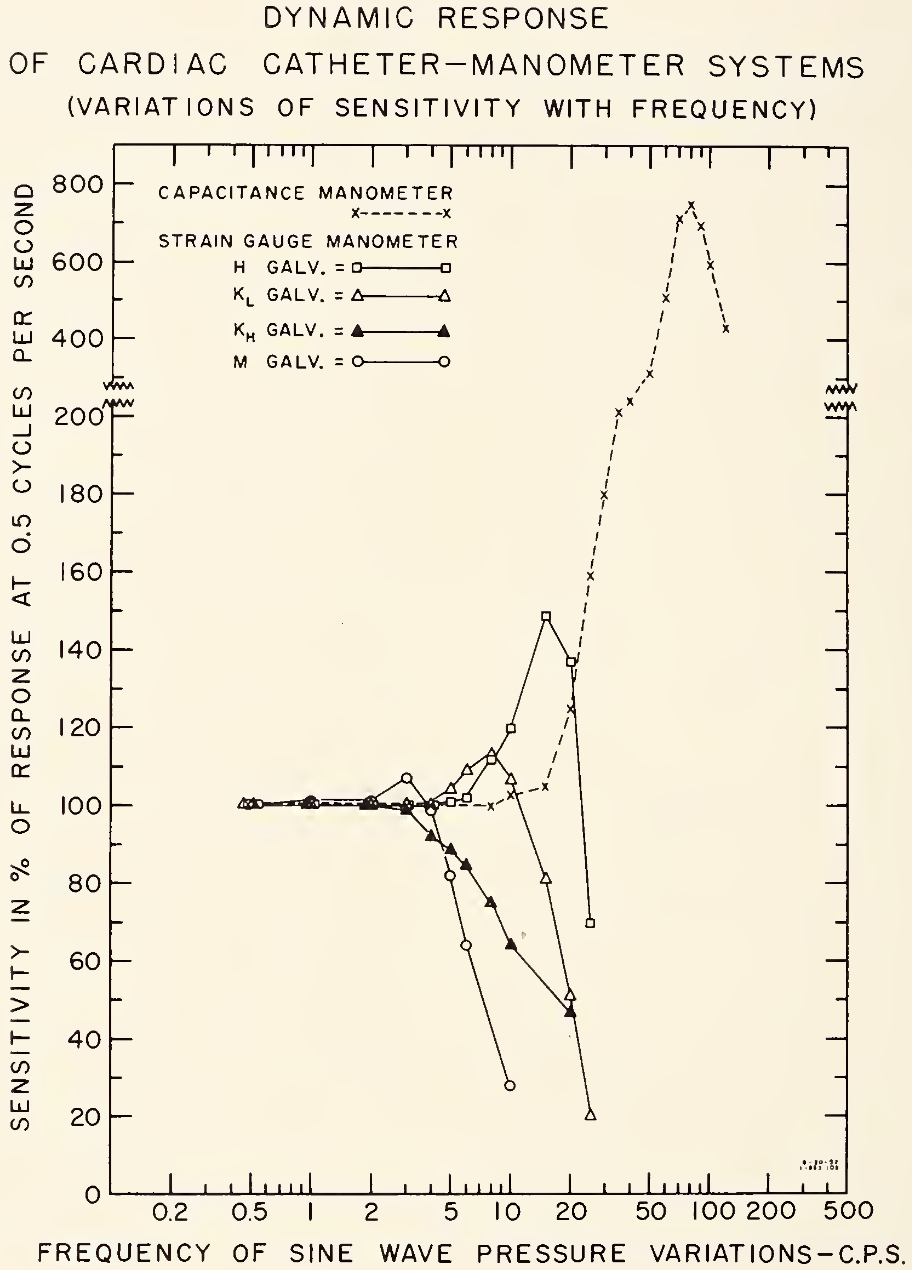

Fig. 1. Variations of sensitivity of cardiac catheter-manometer systems with the frequency of sine wave pressure variations determined immediately after withdrawal of the No. 5 French catheter, 100 cm. long, from the vein (see text for details). The catheter could be connected interchangeably to either a capacitance or a strain gauge manometer. The dynamic response of the strain gauge could be altered interchangeably by connecting it to any one of four different recording galvanometer systems designated as H, K$_L$, K$_H$ and M.

There was an excellent correlation between the degree of distortion of recorded pressure pulses by motion artifacts, and the amount of pressure artifact caused by sine wave, and impact catheter motions produced by the motor-driven cam apparatus. Figures 1, 2 and 3 show typical results illustrating these findings.

These studies were carried out during and after a cardiac catheterization of a six-year-old girl found to have pulmonic stenosis. Pressures were recorded via a 100 cm. No. 5 cardiac catheter from the pulmonary-artery wedge, pulmonary artery, and right ventricle by a strain gauge manometer coupled interchangeably to each of four different galvanometer systems, and by a high-frequency capacitance manometer.

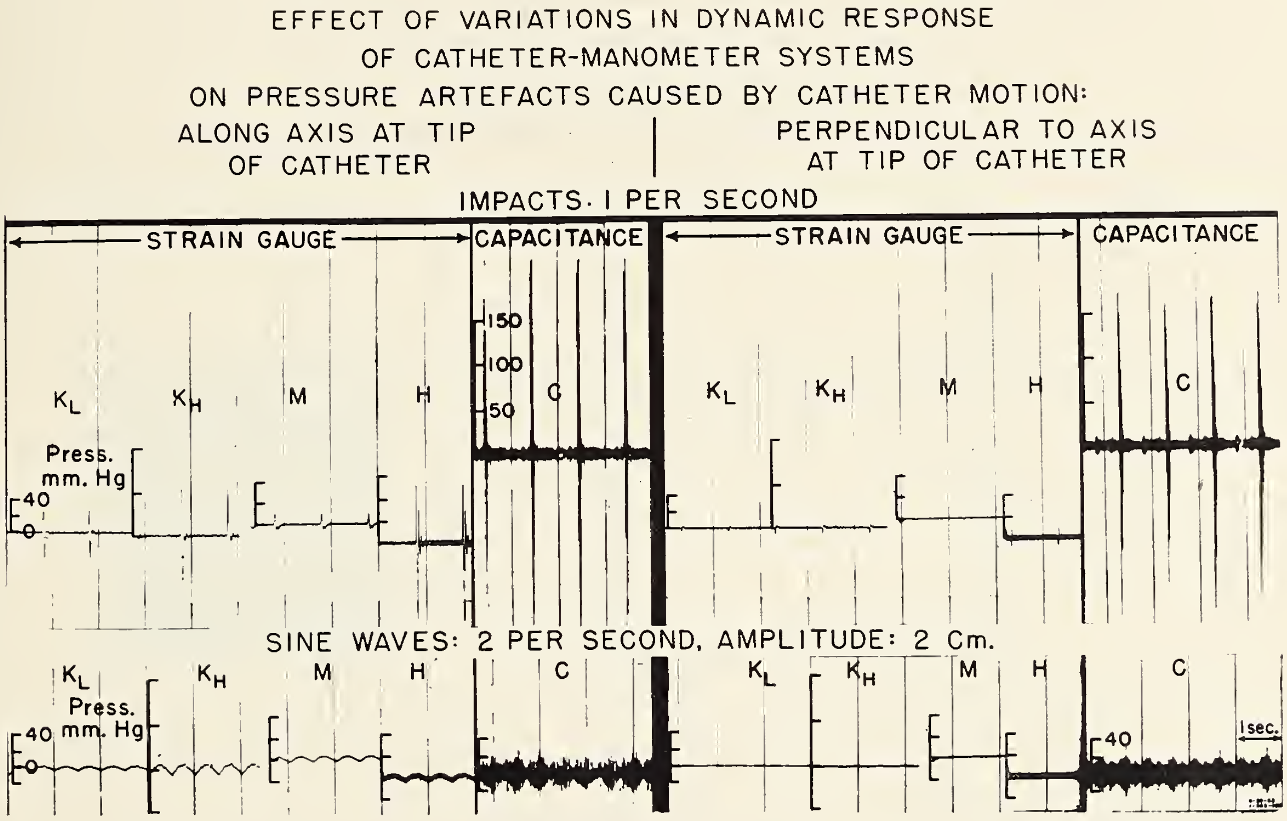

Fig. 2. Effect of variations in dynamic response of cardiac catheter-manometer systems on the pressure artifacts, caused by catheter motion along the axis of the tip of the catheter (left panels), and perpendicular to the axis at the tip of the catheter (right panels). The catheter motions were produced by a motor-driven cam shaft. The dynamic responses of the strain gauge and capacitance manometer systems are shown in Figure 1. Note that the lower frequency strain gauge systems (K_H and M) record less artifact than the 20-cycle system (H), and that the high-frequency undamped capacitance manometer system records continuous high-frequency oscillations probably associated with induced mechanical vibrations in the catheter system. Note also that motions along the axis of the tip of the catheter produce greater pressure oscillations than do identical motions perpendicular to the axis of the catheter tip.

The natural frequency of the capacitance manometer system was 90 cycles per second, and that of the strain gauge-catheter system about 20 cycles per second. By use of lower frequency galvanometers the response could be reduced interchangeably to about 10 or to less than 5 cycles per second (Fig. 1). The susceptibility of these catheter-manometer systems to pressure artifacts caused by motion of the catheter is shown in Figure 2. Since the major portion of the pressure artifacts are caused by the acceleration and deceleration of the fluid column within the catheter, induced by motion of the catheter, it is to be expected that motions along the axis of the catheter generate greater reactive pressures than do motions perpendicular to the axis. Impacts along the axis of the catheter tip caused spikes of pressure varying from 5 mm. of mercury for the overdamped 5-cycle strain gauge system to more than 200 mm. of mercury for the underdamped 90-cycle capacitance manometer system. Sine wave motions at 2 per second of 2-cm. amplitude caused smooth 10 mm. of mercury peak-to-peak pressure variations in the 5-cycle system and continuous noise, 10 to 20 mm. of mercury in amplitude, in the 90-cycle capacitance system. Higher frequency catheter-manometer systems were uniformly more susceptible to motion artifacts than the low-frequency systems.

Pressures recorded by these identical catheter-manometer systems from the pulmonary-artery wedge, pulmonary artery and right ventricle are shown in Figure 3. The most artifact-free tracings were obtained by the 5-cycle system. When the catheter was threaded through the heart into the wedge position, the pressure pulses recorded by the 90-cycle capacitance manometer system were obscured by artifacts.

Tracings obtained by the capacitance manometer can be improved by damping so that the response is limited to 5, 10 or 20 cycles per second. The capacitance and strain gauge systems are then about equally sensitive to motion artifacts. Pressure pulse tracings obtained from the pulmonary artery and right ventricle show the least artifact for the 5-cycle system, most for the 20 and intermediate, and about equal artifact for the 10-cycle capacitance and strain gauge systems.

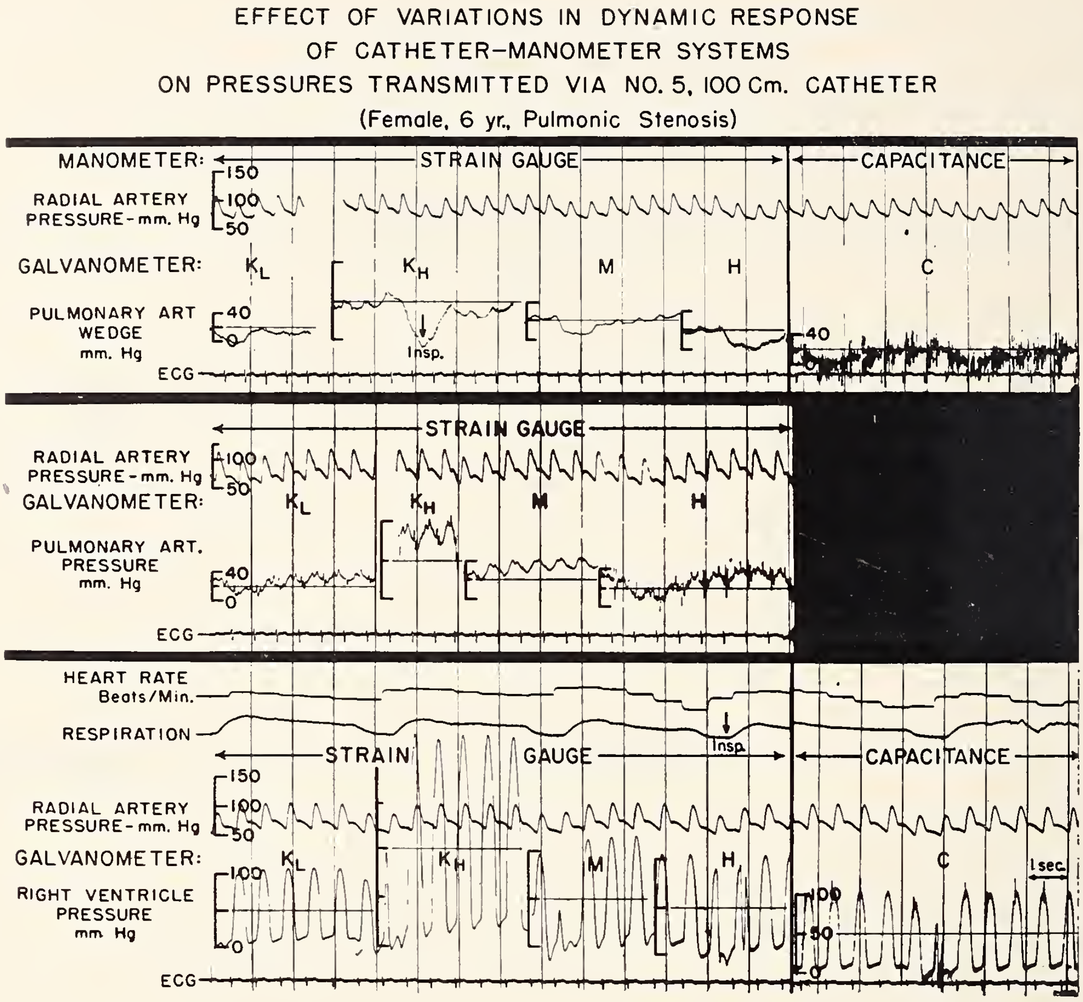

Fig. 3. Effects of variations in dynamic response of catheter-manometer systems on pressure pulses recorded from the pulmonary-artery wedge, pulmonary artery and right ventricle of a six-year-old girl with valvular pulmonic stenosis. The dynamic responses of the strain gauge and capacitance manometer systems are shown in Figure 1. Note that recordings from the lower frequency strain gauge systems (K_H and M), show less evident distortion by artifact than the 20-cycle system (H), and that when the catheter is threaded through the beating heart the pressure pulses in the capacitance manometer recording are almost completely obscured by high-frequency artifact. Note also the correlation between the susceptibility of the various systems to motion artifact shown in Figure 2, and the evident artifact in the pressure pulses recorded by these same manometer systems.

It has been suggested that motion artifacts would be reduced if very small catheters were used or, better still, if pressures were recorded by a small catheter threaded through the standard size cardiac catheter. In our laboratory this has been found not to be the case. The small catheter used was of the Peterson type (145 cm. long, 0.3 mm. I.D., 0.6 mm. O.D.). For pressure recording from the heart it was threaded through a conventional 120 cm. Cournand No. 6 cardiac catheter using a special adapter assembly.

The dynamic response of these systems was determined. The natural frequency of the 0.3 mm. catheter-capacitance system was about 30 cycles per second. For pressure pulse recording the system was damped down to 10 cycles per second, similarly to the standard catheter-strain gauge system. The strain gauge system, recording from the cardiac catheter containing the small catheter, was the most overdamped of the three systems, having a uniform response out to only 2 cycles per second.

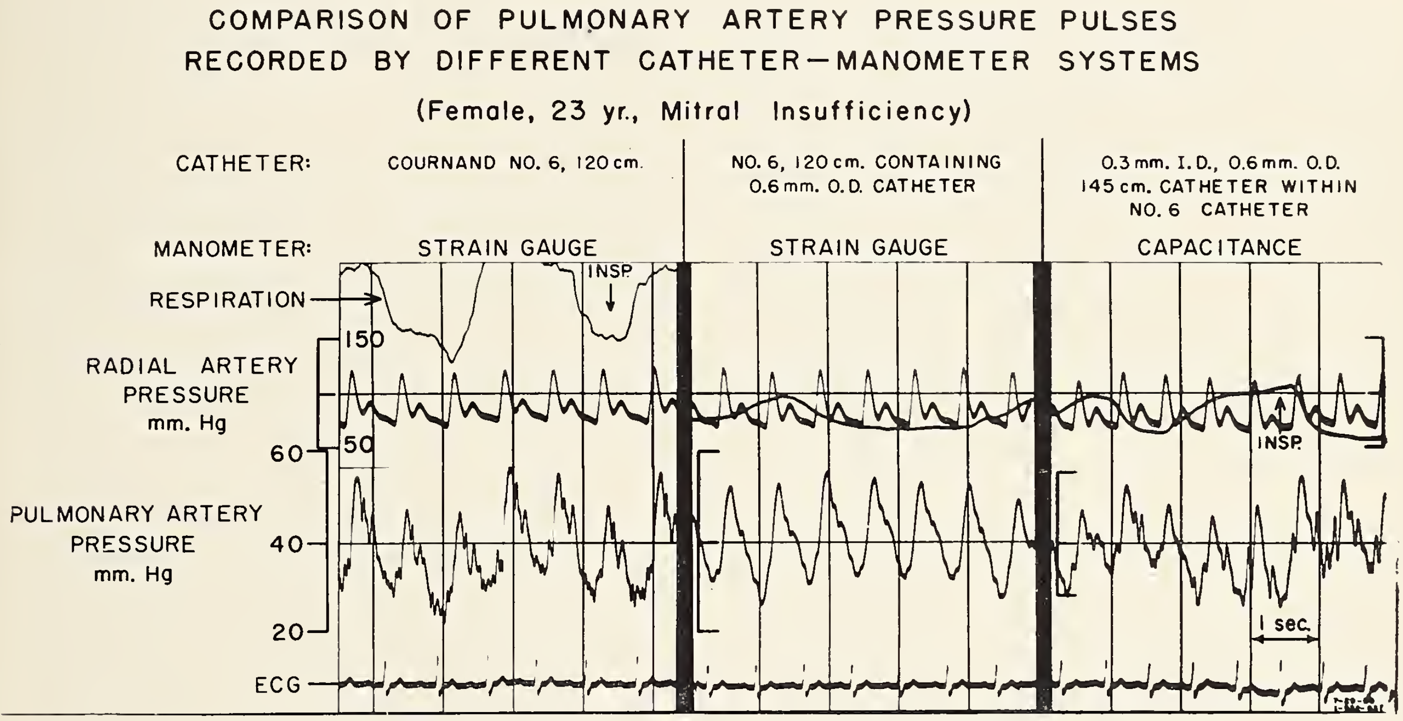

Fig. 4. Comparison of pulmonary-artery pressure pulses recorded by different catheter-manometer systems from a twenty-three-year-old woman with mitral insufficiency. For details concerning the make-up and the dynamic responses and susceptibility to motion artifacts of these three manometer systems, see text. The small plastic catheter was protected from impacts due to the heart action by the No. 6 cardiac catheter through which it was threaded into the pulmonary artery. The pressure pulses recorded by this system (right panel) are nevertheless, still badly distorted by artifact, although somewhat less so than the recordings from the conventional catheter-strain gauge system shown on the left. The frequency response of the overdamped system (strain gauge connected to the No. 6 cardiac catheter containing the small plastic catheter) is probably too low for accurate recording of intracardiac pressure pulses, though the tracings obtained (middle panel) show the least evident distortion.

The susceptibility of these systems to motion artifacts was determined also. The overdamped strain gauge system exhibits the smoothest tracing while the small catheter-capacitance manometer system is intermediate between that and the standard catheter-strain gauge system. Actual pressure pulse tracings from the pulmonary artery of the same patient show similar results (Fig. 4), evident motion artifacts on the small catheter-capacitance tracing being intermediate between those seen on the tracings from the two strain gauge-catheter systems.

Comment

These and similar studies have led us to conclude that it is highly improbable that high-fidelity pressure pulse tracings can be recorded via conventional catheters threaded into the beating heart. The degree of evident distortion can be reduced by using relatively low-frequency recording systems with a sharp cutoff in sensitivity to higher frequencies which thus selectively discriminate against the relatively higher frequency motion artifacts. This requirement is, however, mutually antagonistic to the recording of cardiac pressure pulses, since elimination of evident motion artifact requires such a low frequency system that adequate reproduction of the pressure pulses in question may not be possible. Indeed, motions of the catheter at the frequency of the heart beat, induce pressure artifacts at the frequency of the cardiac cycle which may be relatively smooth in contour and fused with the actual pressure pulse in such a way as to be unrecognizable as artifact.

The only solution to this problem known to us at present, is the use of a miniature manometer attached to the intracardiac tip of the catheter. Such a manometer has been made by Gauer and Geinapp after Wetterer's design.[2] Since its moving element has a mass of only 15 mg., reactive forces to acceleration and deceleration of the catheter tip are very small and hence this catheter-manometer system is practically free of motion artifacts when the catheter is moved outside the body.[1] Pressure pulses recorded from the heart and great vessels are similarly practically devoid of artifact.[1]

Summary and Conclusions

An electromagnetic hydraulic pressure oscillator has been used to study the dynamic response characteristics, and a motor-driven cam apparatus to study the pressure fluctuations caused by reproducible sine wave and square wave motions of cardiac catheters connected to strain gauge or capacitance manometer systems. These studies were carried out immediately after use of these identical systems for recording of intracardiac pressure pulses during forty-seven diagnostic cardiac-catheterization procedures in patients with various types of cardiovascular abnormalities.

1. Sine wave motions, along the axis of the tip of the catheter at a frequency of 2 per second and a peak-to-peak amplitude of 2 cm., produce sine wave variations of pressure at this frequency and with a peak-to-peak amplitude of about 10 mm. of mercury. This motion of the catheter tip resembles that usually seen to some degree at cardiac catheterization, especially when the catheter tip is in the pulmonary artery. Sine wave motion perpendicular to the axis of the tip of the catheter did not produce pressure fluctuations of practical significance.

2. Square wave motions (impacts) produce high-frequency pressure variations of greatest magnitude when the impact is directed along the axis of the tip of the catheter. The amplitude of the recorded pressure variations induced by square wave motion of the catheter (impacts) varied inversely with the frequency response of the catheter-manometer systems used. Impacts of the catheter produced much less pressure fluctuation when in a direction perpendicular to the axis of the catheter than when directed along the axis of the catheter.

3. A close correlation was demonstrated between the susceptibility of cardiac catheter-manometer systems, to pressure artifacts induced by motion of the catheter outside of the body, and the degree of distortion by artifact of pressure pulses recorded by the same catheter system from the beating heart.

4. Catheter-manometer systems, with a uniform dynamic response out to 5 to 10 cycles per second with a sharp cutoff in sensitivity to higher frequencies, were least susceptible to the higher frequency pressure artifacts induced by catheter motion, and likewise produced pressure pulse recordings with the least evident distortion by artifacts.

5. Pressure pulses, recorded by conventional catheters threaded through the beating heart, should be regarded with a high index of suspicion, since the lower frequency artifact induced by motion of the catheter synchronous with the heart beat, may be of such character and be fused with each pressure pulse in such a manner as to be unrecognizable as artifact.

6. Recording of pressures by a small (0.3 mm. I.D.) catheter threaded through a conventional cardiac catheter reduces slightly but not to a sufficient degree the artifact present in pressure pulse recordings from within the heart.

MATHEMATICAL CONSIDERATIONS OF INDICATOR DILUTION TECHNIQUES

C. W. SHEPPARD
Oak Ridge, Tennessee

THE STUDY of circulatory mixing processes is an important practical approach to the investigation of the circulatory physiology of man in health and disease. Injection of substances into the blood stream and observing the time relations of concentration either at the injection site or at other sites is one of the physiological manipulations which can be sanctioned in human studies. With the advent of a growing multitude of tracer substances, there remains an increasing number of experiments of this type which can be done. Their interpretation will require an improved knowledge of the processes of circulatory transport and mixing.

The measurement of volumes of dilution of injected substances will not be emphasized in this discussion. Instead we will consider the immediate events following the rapid injection of a small portion of labeled material into a large vessel. The extensive pioneer work by Hamilton and his associates[5] on the concentration of dye in blood from the radial artery following injection in the cubital vein is familiar to all. Recent developments include the use of radioactive isotopes[1,8,12] and the development of photoelectric recording methods either with the use of the ear oximeter or with the recording cuvette through which blood from a needle in an artery or vein is allowed to flow.[3,10,11]

Although these technical improvements have been of great value, the interpretation of the data which they furnish requires the use of a few mathematical considerations in achieving a quantitative description of both the dispersing processes which occur as the dye flows through the circulatory labyrinth and the effects of recirculation. The present discussion should be considered as an introduction to a problem which has been explored in a preliminary way only, but steady progress is being made and the results seem to justify the effort, at least, so far. We will confine our attention for the moment to substances such as P^{32}-labeled erythrocytes or T-1824 which do not rapidly disappear from the circulation, since it has been shown recently that even rather rapidly disappearing substances yield results which can be expressed in terms of an equivalent nondisappearing substance.[13]

Circulatory mixing represents one of the powerful processes by which the body resists the action of external disturbances which might interfere with the preservation of a stable internal milieu. When a small quantity of injected substance moves through the circulation, we can imagine it to be resolved into a very large number of small elements, each requiring a different amount of time to move through the circulatory labyrinth. The variation in traversal times causes the substance to be randomized and progressively smeared or dispersed in time during the process of circulatory mixing. It is intriguing, perhaps, to realize that here the body architecture achieves design essentially by lack of it. Because of this apparent lack of design, as we usually think of it, the purely deterministic approach is not likely to be fruitful in describing the dispersion process.

One illustration of our limitations, which was particularly instructive, occurred when an attempt was made to investigate the simple case of dispersion of dye during simple laminar flow along a uniform cylindrical tube. The theory of this process is quite simple. Suppose that water is flowing through the tube at the rate of Q cc. per second and that I milligrams of dye are injected in such a way that the initial distribution in the tube is that of a uniform concentration in a thin layer whose plane is perpendicular to the axis of the tube. If the volume of the tube from the injection point to the outflow is V cc., then the concentration of dye (mg./cc.) in any small uniformly mixed sample taken at time t from the outflow will be

$$C(t)\,dt = 0 \text{ for } t < V/2Q \quad \text{and}$$

$$C(t)\,dt = I\,V\,dt/2Q^2\,t^2 \text{ for } t > V/2Q$$

(Equation 1)

Presented in the Symposium on Recent Advances in Cardiovascular Physiology and Surgery, University of Minnesota, Minneapolis, September 15, 1953.

Figure 1 shows a comparison of the results of one attempted experiment with the theoretical prediction. The results do not agree in anything but a qualitative sense. Further investigation showed that it was extremely difficult to establish the required initial distribution. Not only did small differences in specific gravity of the injected dye compared to the water in the tube cause settling of the dye, but also the concentration was not uniform because of the slow mixing of the dye with the water. Since the arrival time downstream of a small dye element depends critically on its initial radius from the center of the tube, the time relations downstream were greatly affected by the nonuniformity of the initial dye distribution, and due to our inability to control the dye, the results were erratic from one experiment to the next. Although this difficulty may be controlled by special techniques, the difficulty in control of the dye applies in all likelihood to a great many typical physiological situations.

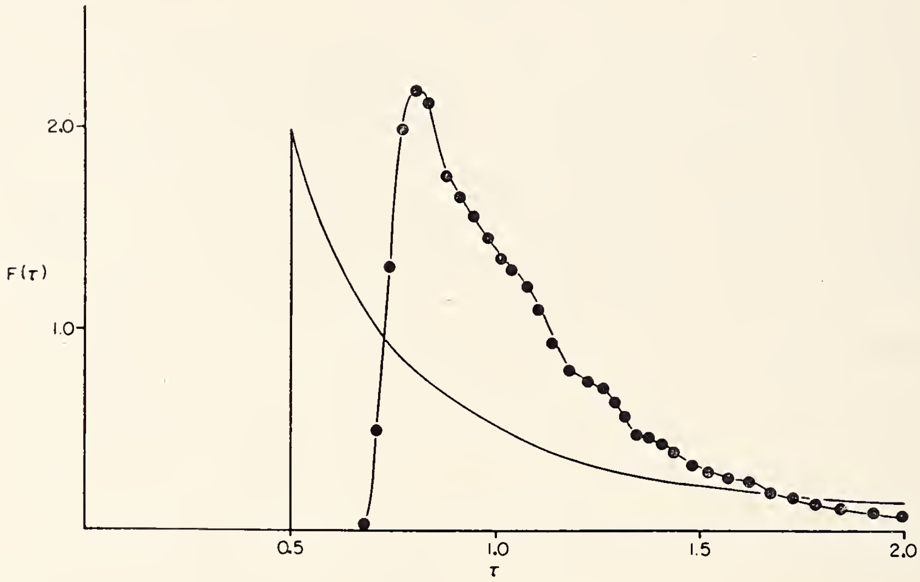

Fig. 1. Theoretical and attempted experimental results on the outflow of a small uniformly injected element of dye from a uniform cylindrical tube in which the transporting fluid moves without turbulence. The experimental results (dotted points) fail to confirm the theory because of uniform inability to control initial distribution of injected dye and to prevent gravitational settling.

Equation 1 can be greatly simplified if we choose a different set of variables. In the first place the concentration in a given sample is not the basic quantity but rather the fraction of the total injected dye contained in it. Secondly, the flow rate, the time, and the bed volume are not individually important variables. Neglecting diffusion and settling out effects, in the ideal situation we can collect the fractions at any rate, or at variable rates, or the experiment can be interrupted and continued at a later time. The factor controlling the situation at the outflow is the volume of fluid collected rather than the time, i.e., the product Qt. If the length of the tube be doubled, the first dye will not appear until twice the volume of water has passed through the system. Thus the basic variable is the fraction of bed volume displaced, i.e., $Qt/V = \tau$. Making these substitutions in equation 1, we obtain the universal relation that the fraction of dye in a given sample for $\tau > 0.5$ is

$$F(\tau)d\tau = C(t)\ Qdt/I = d\tau/2\tau^2$$

(Equation 2)

as before for $\tau < 0.5\ F(\tau) = 0$. This is a universal expression which applies to all uniform bore circular cylindrical tubes irrespective of their dimensions provided the flow is streamline.

It seems scarcely likely that any vestige of organized flow of the type just discussed will remain in the circulation shortly after injection. Even if the settling out effect, and the nonuniformity of the injection process could be controlled, many factors will immediately act to randomize the indicator. A few bifurcations will be sufficient to destroy any regularity which might exist. Turbulence will occur at least in the heart. Most important, however, is the separation of the injected material in the capillaries and the later recombination in a completely undetermined manner. For this reason, we must reject the purely deterministic point of view and turn to the methods of probability in our investigation of the most likely form of F(τ). We thus consider the nonrandom components in a nearly random situation.

The so-called "stochastic" approach based on probability considerations is to consider the type of F(τ) which would occur if the dye elements were being carried through a series of uniformly mixed compartments. There seems to be little anatomical reason to adopt this point of view. Perhaps the outflow from the heart might approximate the situation of two chambers, but nevertheless the advantage of this so-called "washout" model is a theoretical one. From the statistical point of view the dye particles progress through the chain of compartments in a series of jumps. In each compartment a particle makes many trials before it can escape because of the uniform mixing in the compartment. When it finally escapes, this is a rare event. The probability is proportional to the ratio of the flow rate through the compartment divided by its volume. The process of escape from any compartment is not controlled in any way by what happened in previous compartments. In general, when it leaves the n'th compartment, there have been n successes. This problem is a special case of a so-called "Markov chain."[2] It is completely analogous to the problem of radioactive decay of a nonbranching chain of nuclides in equilibrium and its solution is given in standard texts on radioactivity. If all of the dye is initially uniformly mixed in compartment one, then for n compartments

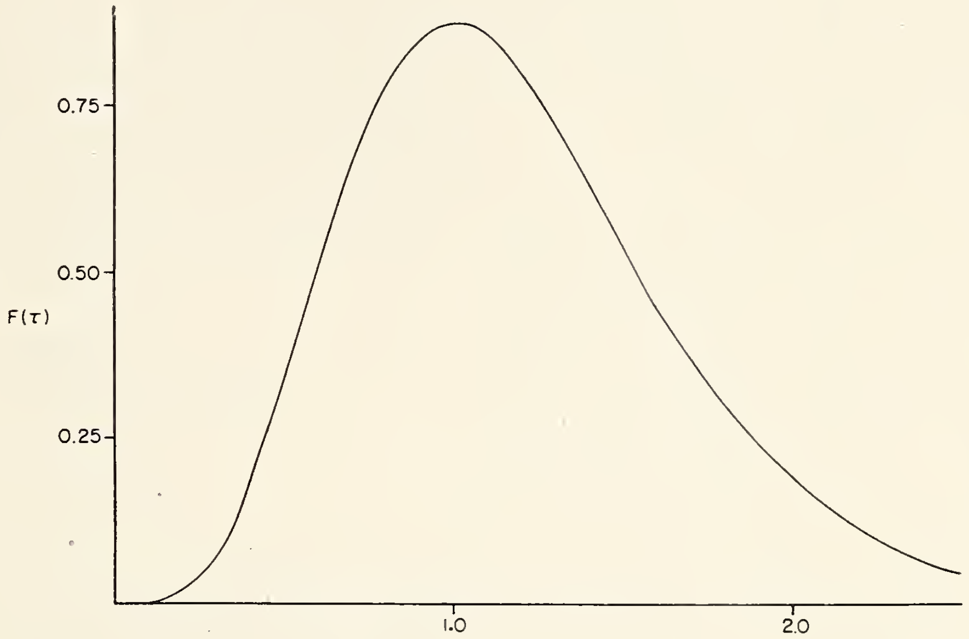

Fig. 2. Theoretical outflow of indicator for a serial system of 5 equal chambers in which uniform mixing is maintained. The abscissa is the fraction of the system volume displaced as fluid passes through the system. The ordinate is the fraction of injected indicator per unit τ interval appearing at a given τ instant.

$$F(\tau)d\tau = \sum_{i=1}^{n} f_n \frac{f_i^{\,n-2}}{f_i \prod\limits_{\substack{j=1 \\ j \neq i}}^{n} (f_i - f_j)} e^{-\tau/f_i} d\tau$$

(Equation 3)

where f_i is the fraction of the system volume in compartment i.* If the compartments are all alike the solution becomes

$$F(\tau)d\tau = \frac{n(n\tau)^{(n-1)}}{(n-1)!} e^{-\tau n} d\tau$$

(Equation 4)

Since for n compartments we are dealing with the probability of n-1 successes in a series of independent equally likely trials of a rare event (i.e., the successive escapes from all but the last), the fact that we have obtained the Poisson law of probability is not surprising. In general, we should consider the Function $F(\tau)$ as a typical statistical frequency distribution function which, when multiplied by $d\tau$, gives the fraction of the total dye elements appearing in a given small class interval $d\tau$ of the independent variable τ.

---

*The π in the denominator signifies "the product of a set of factors each corresponding to a given integral value of j ranging from 1 to n but omitting the factor in which j and i are alike."

Figure 2 shows a typical plot of $F(\tau)$ for a system of five equal compartments. It is evident that the curve has some resemblance to typical curves of the outflow of dye from the pulmonary circuit in man and in the dog. This led Newmar and his associates to postulate that often dispersion curves were adequately described by the "washout" theory.[10] It seems, however, that this agreement is the result of a statistical accident. One can scarcely believe that the movement of dye through a capillary bed and extensive system of branching vessels is the result of a small number of successes in a series of trials of a rare event. Instead of a few large jumps and long pauses in the progressive movement of the dye elements, it is eminently probable that a closer representation is given by a theory that considers a very large number of rapidly occurring small jumps. Under these conditions, the probability theory predicts that the particles will execute a "random walk."[2] Random walk problems have received considerable attention in the literature, but most mathematicians consider the situation of a fixed probability distribution for the jumps. This classical version of the random walk will serve as a first approximation to the physiological situation. We will consider it first and discuss the corrections to the theory separately.

A good experimental illustration can be obtained by filling a long uniform tube with 3 mm. glass beads, allowing water to flow through it and injecting a small amount of dye in one end. At the beginning the dye forms a small compact slug at one end of the tube. As the fluid moves through the beads some dye elements begin to move ahead and others to lag behind. The distribution of dye at various distances along the tube appears to be Gaussian, i.e., that of the normal curve of error. As the center of gravity of the distribution proceeds along the tube with essentially the same velocity as the average fluid velocity the dye spreads out and the standard deviation incerases in proportion to the amount of fluid which has passed through the tube. At the end of the tube the beads suddenly come to an end and so the dye can only cross the boundary once, being immediately swept away. A dye element is thus said to execute a random walk terminated by a first traversal. Because of the effect of the end of the bead column and because the standard deviation increases with the volume of fluid which has passed, the distribution of dye among the various fractions collected will not be Gaussian. The relation which can be derived from mathematical considerations[2] is

$$F(\tau)d\tau = \frac{e^{-\frac{(1-\tau)^2}{\kappa^2\tau}}}{\kappa\sqrt{\pi}\,\tau^{3/2}}\,d\tau$$

(Equation 5)

The randomizing constant $\varkappa$ represents $\sqrt{2}$ times the standard deviation relative to the mean of the dye distribution which would be obtained if, after the displacement of one bed volume, the experiment were stopped and if the various fractions could be removed from the tube and their label content determined without disturbing the distribution. $\varkappa$ is expressed in units of τ. In deriving this relation it is assumed that the center of mass of the distribution moves with the same velocity as the liquid, i.e., the probability distribution for the movement of the dye elements relative to the fluid is the same forward as backward.

The classical random walk problem is of general interest. In the theory of games of chance it is often called the Gambler's Ruin problem, since it describes the progress of a game in which a player contends with an infinitely wealthy opponent who has the odds in his favor. It has been used in physics to describe the Brownian movement of a particle. The background mathematics is found in a number of standard texts.[2] The problem is a special case of a Markov chain but is often developed as a limiting case of the random movement of particles between isolated points on a line as the points become infinitely numerous and close together. Particles are permitted to jump to a distant point or to neighboring points. It is required that no jump is in any way affected by previous jumps. Jumps of different amounts are not required to be equally probable but whatever the pattern of probability of the jumps in the classical version of the problem it must be the same for all. The jumps are random in that their magnitudes cannot be predicted but merely the relative likelihood of a given sized jump. Jumps forward can be more frequent or less frequent than jumps backward. The degree of asymmetry will govern the rate at which the centroid of the population will move. The rate of increase of the standard deviation will be governed by the root mean square of the magnitudes of the jumps and the rate at which they occur. This will be determined by the magnitude of the proportionality constant in the denominator of the exponent. This will be the randomizing constant $\varkappa$ in equation 5. In a fine grained bed $\varkappa$ would be larger than in a coarse grained one, and ideally determining $\varkappa$ would yield valuable information.

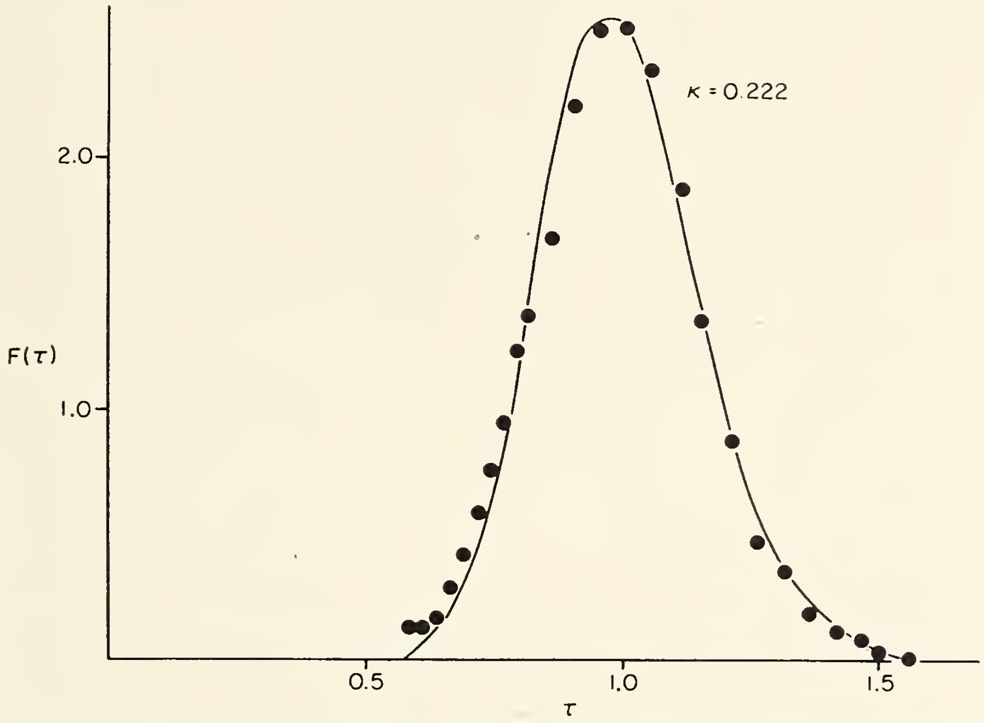

Fig. 3. Comparison of experimental results for outflow from a long cylindrical bed of uniform glass beads (●) with a theoretical one dimensional random walk curve (—). The water volume in the bed was 193 cc. See Figure 2 for ordinates and abscissas.

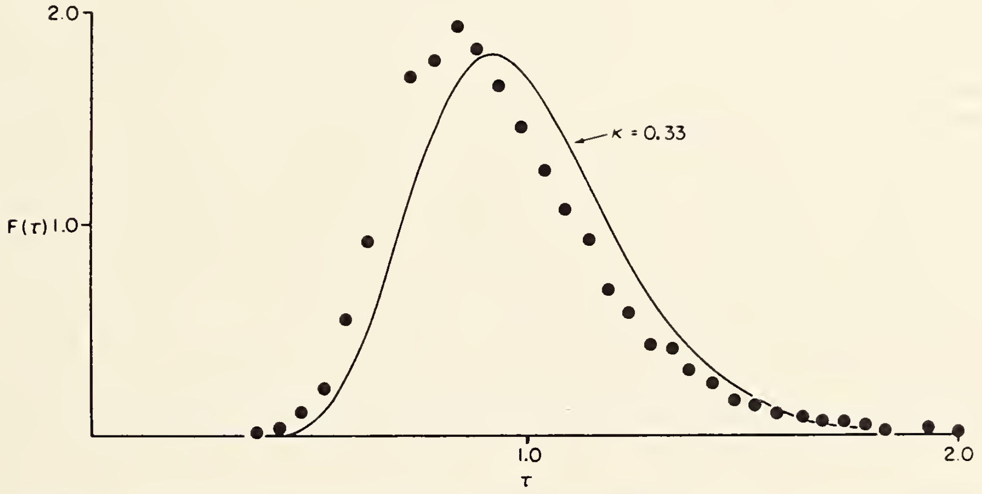

Fig. 4. Similar comparison (see previous figures) for a spherical flask containing 3 mm. beads. The water volume was 193 cc.

Comparison of theory and experiment (Fig. 3) indicates satisfactory agreement in the case of a long thin tube filled with glass beads, but this is quite unrealistic as a description of the flow through a physiological labyrinth such as the pulmonary circuit. In the first place, the shape of the bed plays a role. The outflow of dye from a spherical vessel is shown in Figure 4. The water entered a spherical bulb flowed through the same size beads as in the tube experiment and was collected immediately at the outflow. The result systematically deviates from the random walk hypothesis, but it serves as a first approximation even though in this case the dye elements are not confined into a linear path for their excursions. The value of $\varkappa$ is significantly greater than for the linear tube case although the same size beads were used. Some improvements of fit could probably be achieved by introducing an effective bed volume and starting time, adopting the variable τ' which would be the fraction of the *effective* bed volume which has flowed through the system.

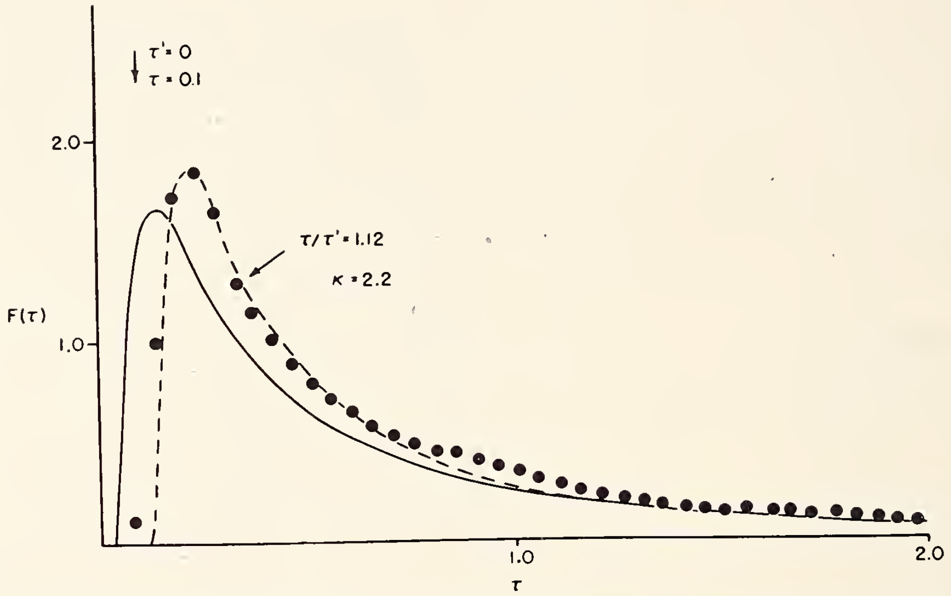

Fig. 5. Spherical flask (Fig. 4) with exit pipe projecting into the center.

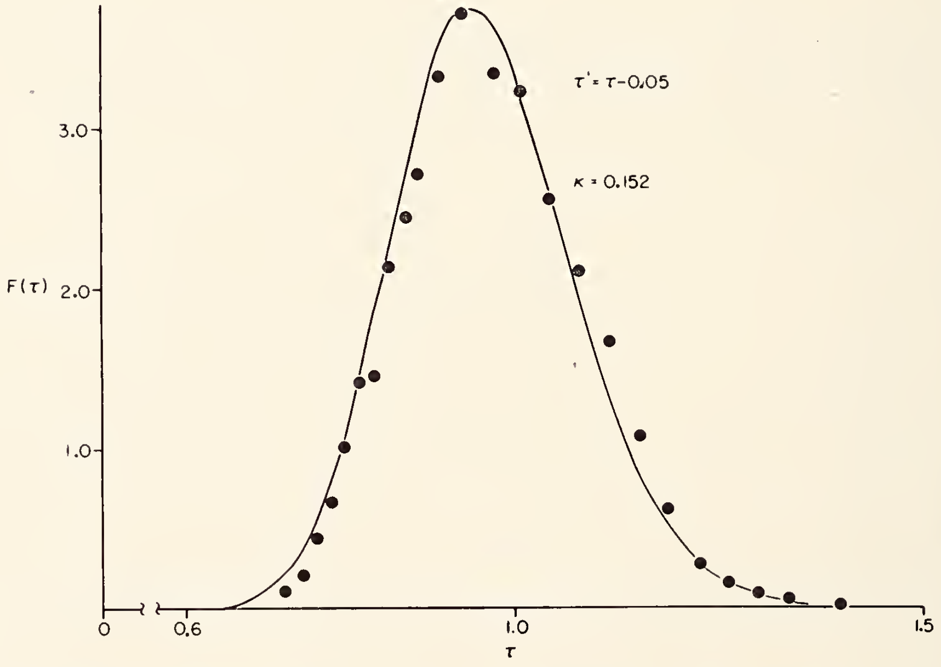

Fig. 6. Same as Figure 3, but dye injected in the rubber supply tube 71 cc. upstream.

When a deliberate attempt was made to produce a severe distortion of flow from that of a straight tube the shape of the curve could be strongly influenced. Instead of allowing the fluid to emerge directly from the bulb, a tube was inserted so that its orifice was at the bulb center. Under these conditions (Fig. 5), there was a large increase in the value of the randomizing constant. Furthermore, to fit the theoretical curve, the volume of the water in the bulb could no longer be used but instead an effective volume 12 per cent greater had to be introduced, together with an effective starting time at $\tau = 0.1$.

The preceding experiments all involved a uniform randomizing structure in the bed. Dye was injected directly at the inflow, traversed a collection of uniform beads, and was collected with as short an outflow tube as possible. This, of course, ignores the fact that in a physiological system the volume of the vessels leading into the system is appreciable. Often, also the material must be collected through a long catheter, whose dispersing effect on the dye must be considered. Since the sum of the randomizing effects of a series of different dispersing systems should be independent of the order in which they occur, a long inflow or a long outflow tube should produce similar effects. To investigate the effect of a long entrance tube, the cylindrical container containing the 3 mm. beads was equipped with a 3-meter rubber tube of approximately 5 mm. 1.D. Dye was injected into the upstream end and the outflow curve determined (Fig. 6). There is also a small 5 per cent correction for effective injection time. The curve is a fairly good fit to a random walk relation using a value of $\varkappa$ derived on the assumption that the equivalent $\varkappa$ for the tube is negligibly small. Since the flow through the tube is not well approximated by a randow-walk relation, a good deal of further research must be done before such an effect can be entirely understood.

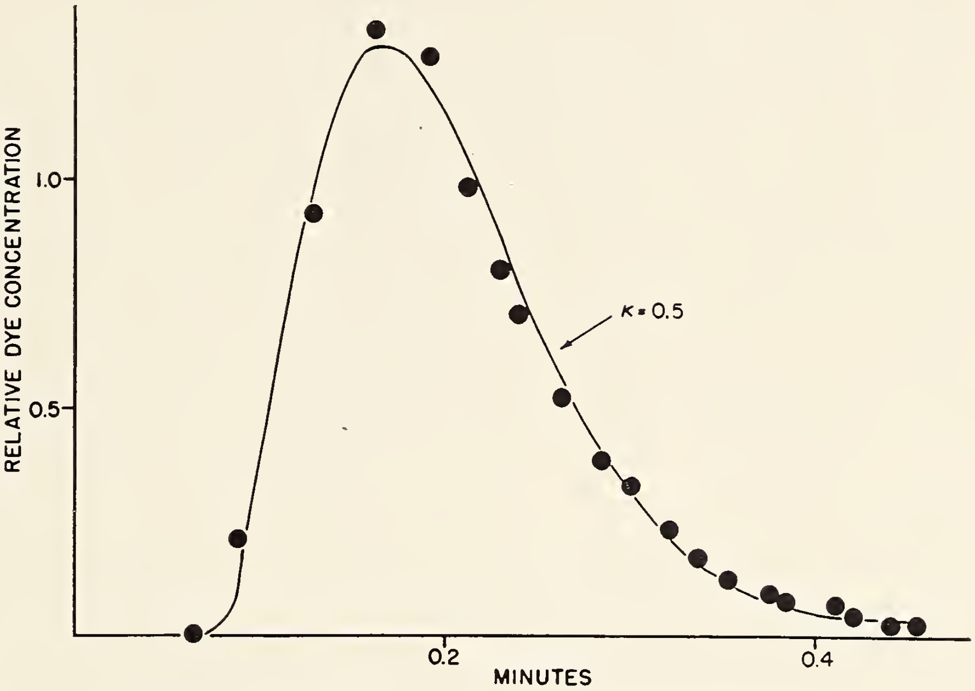

Fig. 7. Data of Hamilton *et al,* for perfused isolated heart-lung preparation in a dog.

It was recently suggested by L. J. Savage and the author[14] that the one-dimensional random walk might serve as a first approximation to the problem of capillary outflow. Applications of the theory to physiological data are limited as yet because most of the curves have been taken from beds of unknown volume, so that at least two constants can be invoked in fitting the data. This gives more latitude than the theorist deserves. Figure 7 shows a comparison between the theory and experiment for data obtained by Hamilton et al.[5] who perfused an isolated heart lung preparation in the dog. A rather satisfactory agreement was obtained using a value of $\varkappa = 0.5$. However, a rigorous test of fit is not possible because the readings were obtained by enlarging the small figure in their paper which produces some transcription error. A similar curve obtained more recently by Howard, Dow, and Hamilton[6] is closely similar if the appropriate scale adjustments are made. Again a fair agreement is obtained. A second experiment which they performed on the same preparation gave essentially the same result. Unfortunately, a comparison between the effective bed volume and the true volume of blood in the pulmonary circuit is lacking since the latter volume was not obtained. Analysis of the curves using the flow rates, which they actually determined, yields only the effective volume.

When we turn to curves obtained on the lungs alone a different situation is observed. Three injections in one preparation and two in another gave similar results if the probable difference in the cardiac output and volume of pulmonary blood in the two dogs and the variation in amount of injected dye are taken into account. A representative curve together with a fit to the random walk expression is shown in Figure 8. It is seen that to obtain a satisfactory agreement a considerably delayed effective injection time must be introduced. This is also true but to a somewhat lesser extent for a curve obtained by Little and Kelly who perfused an isolated canine liver preparation. The data were obtained in the course of other recently published studies on colloidal gold removal by the liver[7] (Fig. 9). Although the volume of blood in the liver was not known, the value of 240 cc. required to fit the data using their lowest flow rate seems high even for the approximately 16 Kg. dogs which they used. Because of these factors the one-dimensional random walk relation is probably only a first approximation to the true curves, and may often require the inclusion of effective

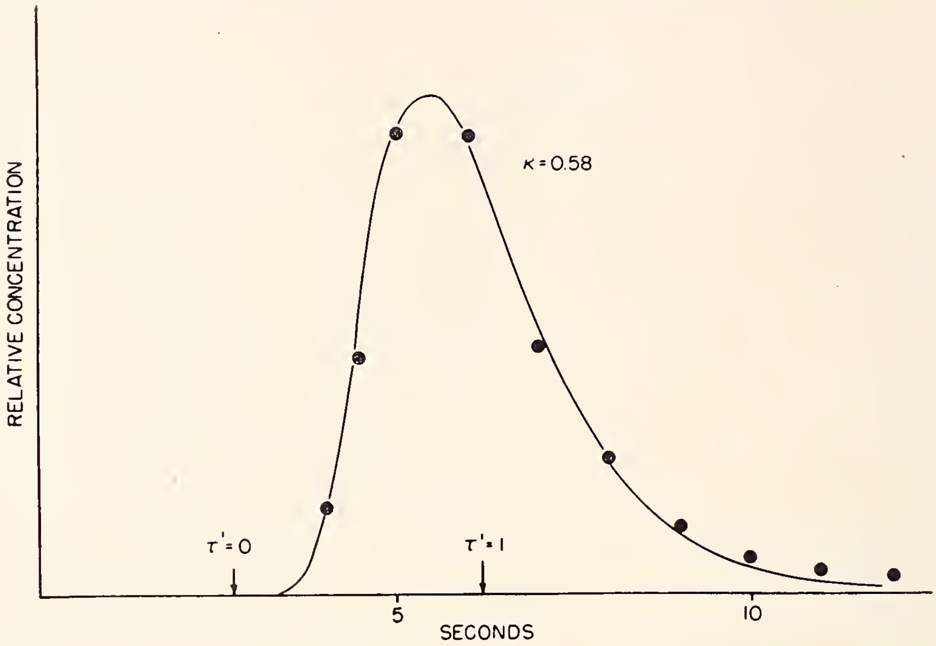

Fig. 8. Data of Howard, Dow, and Hamilton for perfused canine lung without the heart.

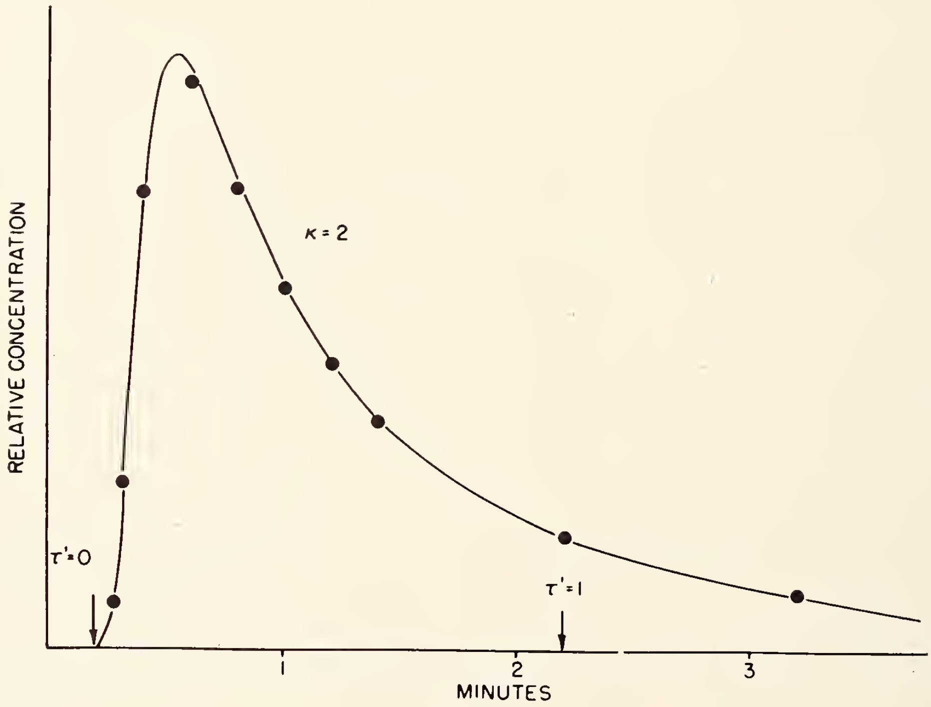

Fig. 9. Data of Little and Kelly for a perfused isolated canine liver.

volumes and injection times in its use. A more complete analysis would consider the movement of dye in terms of a more general Markov problem, but first it would be necessary to get a better idea of the variation in probability distribution of the jumps of the elements of dye as they traverse the circulation.

In addition to the form of the outflow of dye during a single perfusion experiment, we must consider the manner in which recirculation is taken into account before we can discuss the actual process of circulatory mixing. Time will not permit the discussion of recirculation problems in general, but the familiar situation where indicator is injected essentially into the right heart, and samples are taken from the aorta or a close tributary will be sufficiently illustrative. The first step in the analysis is to relate events upstream at some point 1 to events downstream at 2. We will suppose that a small amount of dye is injected suddenly at 1. Let the average concentration of dye be a(0) and the mean duration of the injection Δt. The product of these two factors will be the area under the injection curve. This area, when multiplied by the flow rate Q, will give the amount of indicator injected. We will consider only the case where the injection curve is a very high and very narrow spike. If the dye is injected at zero time, then in the limiting case where the height is infinite and the width infinitesimal (the case of the so-called "delta function"), the time distribution of dye downstream will be the distribution of traversal times, i.e., F(t) and so the concentration at any time t is given by the relation

$$a_2(t) = a(0)\,\Delta t\,F(t)$$

(Equation 6)

This will relate events at 2 to those at 1 provided that there is no dye between 1 and 2 at the moment of injection. If we consider a more general problem, suppose that the time relation upstream is not that of a single spike but a continuous variation given by the relation $a_1(t)$. Then downstream at 2 we will have

$$a_2(t) = \int_0^t a_1(t-T)\,F(T)\,dT \ + \ \text{effect of dye}$$

(Equation 7)

between 1 and 2 at or before $T = 0$. The variable of integration T represents the various time delays of the individual paths between 1 and 2. The second term will be zero if there is no dye in the system before the experiment is begun. The integral is known as a "convolution integral." It is of general utility when it is desired to consider at some point downstream what the effect will be of the smearing of the earlier time relations occurring at some point upstream, when there are the variable traversal times between the two points.

If recirculation is complete, it is postulated that points 1 and 2 coincide in a closed circuit, becoming a single observation point so that

$$a(t) = \int_0^t a(t-T)\,F(T)\,dT \ + \ \text{effect of first circulation.}$$

(Equation 8)

The second term is required because all recirculation effects at the point of observation arise from effects one circulation earlier. The dye already in the loop during the previous circulation will be included only after one initial circulation has occurred. The added term is merely the time relation for one traversal of the labyrinth which for a sudden injection is given by equation 6 so

$$a(t) = \int_0^t a(t-T)\,F(T)\,dT \ + \ a(0)\,\Delta t\,F(t).$$

(Equation 9)

This is an integral equation in which given F(t) and $a(0)\Delta t$ we find a(t). It is so called because the unknown function to be found in solving the equation is related to its own integral which includes the function F(t) called the "kernel."

The solution of the equation involves a principle which is of such potential utility to circulatory physiology that some discussion is warranted. The considerations are based on the so-called "method of Laplace transforms" which is discussed in books on electrical transient analysis.[4] We multiply both sides of equation 9 by e^{-kt} and integrate with respect to t from 0 to ∞. In so doing we convert a (t) to its Laplace transform $\alpha(k)$. Since we have introduced the variable k and removed t by integrating it out, the transform is a function of k. The reason for this maneuver is that the transform of a convolution becomes the product of the transforms of its components which greatly simplifies the solution of the equation. Thus in equation 9 we have simply

$$a(k) = a(k)\,\Phi(k) + a(0)\Delta t\,\Phi(k)$$

(Equation 10)

where $\Phi(k)$ is the transform of $F(t)$. Simple algebra yields the transform of the solution of the equation, namely

$$a(k) = a(0)\Delta t\,\Phi(k) / [1 - \Phi(k)]$$

(Equation 11)

The transform is converted back to $a(t)$ by the process of inversion, which is facilitated by the use of tables of transforms and their inverses which are available.[4,9] The first discussion of the method of Laplace transforms in the study of indicator dilution techniques was given by Stephenson.[15]

In the present case the quantitative discussion of complete circulatory mixing would require a knowledge of the kernel $F(t)$ for the entire circulation from the right heart through the pulmonary and systemic circuits and returning through the vena cava. This is not known but as a first approximation we could assume it to be similar to a random walk curve, taking for k the same value as for the pulmonary circuit. The result could then be reduced to time variables by the use of standard cardiac output and plasma or blood volume figures.

Although the random walk curve is based on a rational set of theoretical assumptions, the curves are not very different for a set of equal uniformly mixed serial compartments, and the transforms for these latter expressions are much simpler and easier to handle. We accept the form of equation 4, but consider n now rather than κ as an empirical parameter and choose τ rather than t for the independent variable, thus we have

$$F(\tau) = n(n\tau)^{(n-1)}\,e^{-n\tau} / (n-1)!$$

$$\Phi(k) = n^n / (k+n)^n$$

(Equation 12)

whose transform by simple algebra is

$$a(k) = a(0)\Delta\tau / [(k/n+1)^n - 1]$$

(Equation 13)

This can be inverted by separation into partial fractions yielding $a(t)$. The case of $n = 4$ will serve as an illustration, thus

$$a(k) = a(0)\Delta\tau / [(k/4+1)^4 - 1]$$

$$= \frac{a(0)\Delta\tau}{2}\left\{1/\left[(k/4+1)^2 - 1\right] - 1/\left[(k/4+1)^2 + 1\right]\right\}$$

(Equation 14)

From tables[4] this yields

$$F(\tau) = \frac{a(\tau)}{a(0)\Delta\tau} = 2e^{-4\tau}[\text{Sinh } 4\tau - \text{Sin } 4\tau]$$

(Equation 15)

Figure 10 shows a plot of this relation. A similar plot is shown for $n = 8$ (Fig. 11).

The theory describes recirculation phenomena at the right atrium but the majority of observations are taken in the aorta, and thus it is necessary to add the further smearing or dispersing effect of the pulmonary circuit. This is simply done by multiplying the transform in equation 14 by the additional transform for the pulmonary circuit. Again we assume the same form for the local portion as for the over-all circulation, but consider for the moment that the volume of the pulmonary portion is some fraction f of the total. The resulting composite transform for observations in the aorta is

$$\frac{a_a(k)}{a(0)\Delta\tau} = \left\{\left[(k/n+1)^n - 1\right]\left[fk/n+1\right]^n\right\}^{-1}$$

(Equation 16)

For $f = \frac{1}{3}$ and for $n = 4$ or $n = 8$, the inverses are shown in Figures 10 and 11. As before, the solutions include only the component after one passage and the first passage contribution must be added. The entire solution is also included in the figures and the curves are not unlike the experimental results so often observed.

Many points remain to be investigated. Time will permit only a brief mention of a few. Little has been said about the transition effects which occur when two randomizing beds with widely different κ's are placed in series. What in general is the effective κ of the combination? The effect of two random walks in parallel is the same as that of a single equivalent one, only if the flow is shared between the two members in proportion to their volume. What kind of linear random walk do we have if $\varkappa$ varies smoothly through the labyrinth according to some prescribed functional relationship? What can we say about the 3-dimensional random walk when the particle can wander sideways into regions of faster or slower flow?

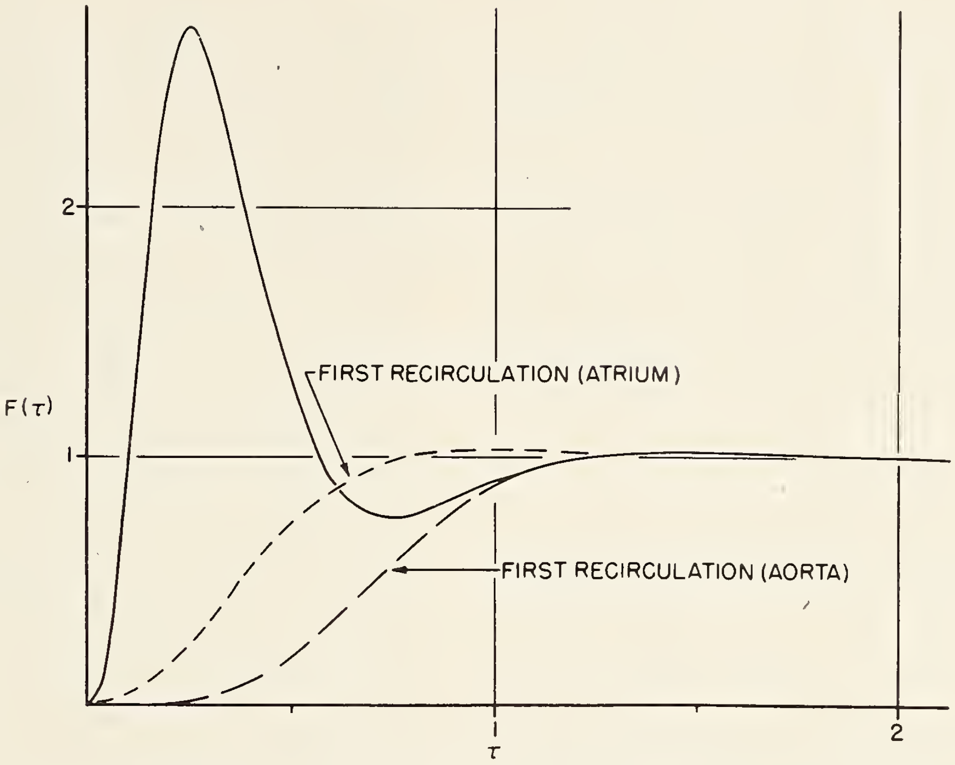

Fig. 10. Solution of the recirculation problem (see text). Solid curve represents theoretical dye curve for injection in the right atrium and observation in the aorta. Dotted curves represent recirculation observed in the atrium and aorta. Distribution in traversal times through the circulation approximated by the relation for the Poisson probability of three successes.

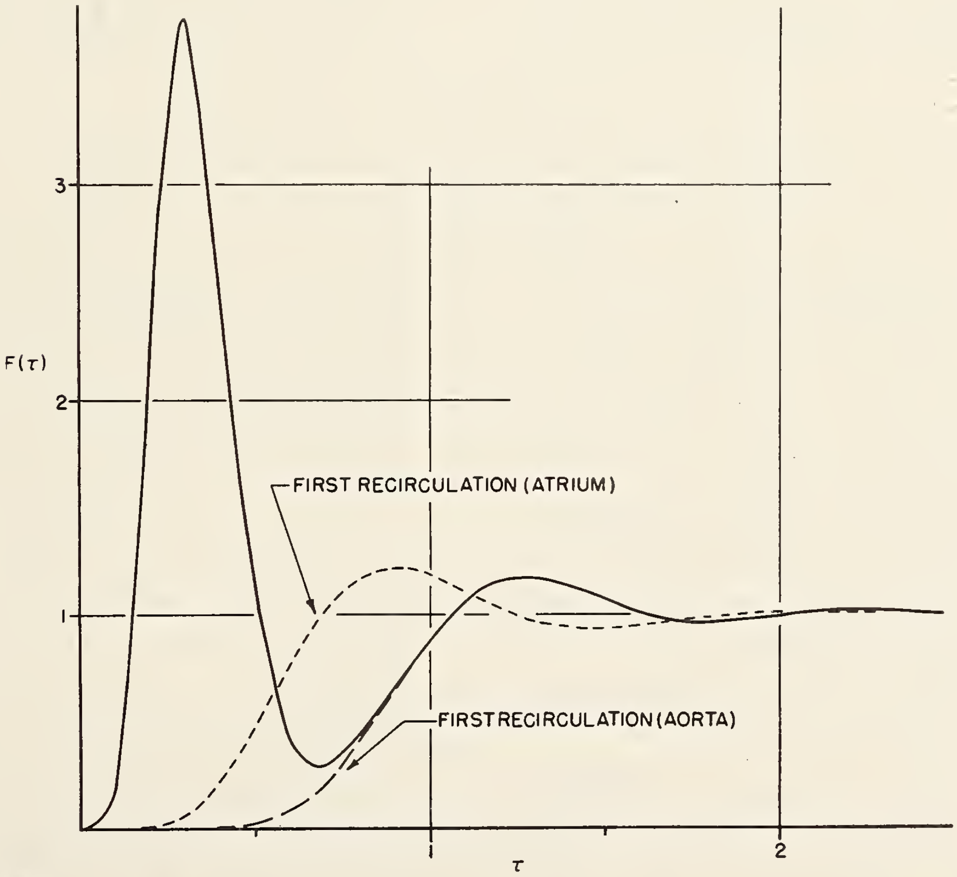

Fig. 11. Same solution as Figure 10 but for seven successes. Note the effect of the increased peaking of the traversal time distribution.

From these considerations alone we see that the present calculations are far from being a complete analysis of circulatory mixing processes. However, they seem to be at least partially successful, and it may be that a rational approach to the study of circulatory transients can be achieved in this way. In any event the results are interesting and the initial successes are sufficient to justify further work of this nature.

In conclusion, I wish to acknowledge the kind assistance of Drs. Howard, Dow, and Hamilton for the canine pulmonary outflow data, and Dr. Robert C. Little for the data on the canine liver perfusion. Some of the laborious numerical calculations were performed by Mr. George Atta of the ORNL Mathematics Panel.

THE RELATION BETWEEN THE STROKE VOLUME AND THE PULSE PRESSURE

JOHN W. REMINGTON
Augusta, Georgia

IT would be well nigh impossible to trace the origin of the notion that the pulse pressure is directly related to the stroke volume. Every physician who places his fingers over the radial artery, does so with the firm conviction that the strength of the beat he feels is set by the amount of cardiac discharge. Our province in this symposium is to see to what extent this subjective impression can be set into quantitative terms. Near the turn of the century, the first step in such a quantitation came with the technology with which pressure excursions in man could be approximately determined in millimeters of mercury. Shortly after, Erlanger and Hooker[2] noted that when the pulse pressure, so recorded, was multiplied by the heart rate, the product tended to be reasonably constant. In those conditions where the cardiac output was presumed to be increased, the product was elevated. Conversely, when the total flow should have been low, as after hemorrhage, the product was decreased. This implied that the pulse pressure was varying directly with the stroke volume. Since cardiac output of man was not, at that time, measurable, physiological conclusions reached on the basis of the change in product were entirely speculative. The quantitative testing fell to workers using the most common method of assessing stroke volume, the cardiometer. On the basis of their work on open-chest animals, they rather promptly discarded, almost *in toto,* the notion that stroke volume could be predicted with any reasonable accuracy from the pressure change. Explanations for this seemingly illogical failure were not clearly put, which perhaps explains why newer generations of physiologists have not remained convinced that the problem is hopeless.

Upon hindsight, we could construct a rather forceful story for the cardiometer workers, with most of the points used, taken from work already published before their investigations were done. In 1880, for example, Roy[12] reported volume-pressure measurements for segments of aortas which showed that the volume equivalent of a given pressure change was different at different pressure levels. This nonlinearity of the volume pressure curve should have been obvious. Even if the aortic wall followed Hook's Law in its stretch, and showed a linear tension-length relation, conversion of tension to pressure would be through the first power of the radius, and of length to volume through the square of the radius, so that the volume-pressure relation must now be curved. Since the aorta does not follow Hook's Law, the curvature is even more pronounced. The volume gain per unit pressure rises therefore increases as pressure rises from 0 to 30 to 40 mm. Hg, after which it becomes approximately constant. At a pressure level of about 100 mm. Hg, the volume gain becomes progressively less. This second inflection is attributable to the complex architecture of the aortic wall. The physician is certainly well aware of it, for he would not think of ascribing an enormously large cardiac discharge to a hypertensive pressure excursion of, say 270/130. For some curious reason, some experimental workers tend to ignore it, and assume a straight-line relationship between volume and pressure obtained at all working pressure levels.

Unfortunately, these inflection points do not lie at the same pressure levels in all individuals, so that there can be no common prototype curve applicable to all aortas. In addition, intra-individual differences in aortic size are quite large. In a group of nine dogs, for example, at a diastolic pressure of 75 mm. Hg, the total aortic volumes varied from 19 to 39 cc., the larger value representing a departure of 39 per cent from the mean of 28 cc. One factor contributing to this variation must be body size. We cannot tell from our data whether this variation with size would be better related to body weight or to surface area. Since we are accustomed to expressing cardiac output in terms of surface area, all arterial bed volumes were corrected to figures per sq. M. body surface. When the above dog aortic capacities were so

---

The investigations reported here were supported by grants from the National Heart Institute, National Institutes of Health, U. S. Public Health Service, and from the Life Insurance Medical Research Fund.

revised, the largest error in the group was reduced from 39 to 29 per cent. Variability still remaining after such a size correction has been made, can be laid to congenital differences or to the effect of age. Roy had mentioned that an aortic segment from a young individual showed a different distensibility pattern from that of an older person. This effect of age was later emphasized in greater detail by Hallock and Benson,[3] who, by publishing only average curves, gave the impression that the change was a progressive and orderly one. When we surveyed a group of forty-eight human aortas,[11] we found that the capacity change with age was only a trend, and that the degree of overlap between age groups was very large. This variation can perhaps best be stated by the fact that we found a "young" aorta in a man of sixty-eight, and an "old" one in a girl of eighteen. Roy reported something which I do not believe has been repeated since, that after a long wasting disease, the dog aorta showed the stretch curve of an "old" aorta. It is quite possible that the variations with age are reflecting not the actual years of life, but rather the history of the number of periods of disease and circulatory stress. Certainly the enlargement often attendant upon hypertension can be seen in both the young and old individual.

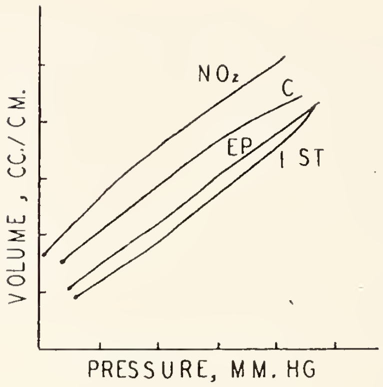

Fig. 1. Volume-pressure relations for a ring of ascending aorta as first removed from the body (1st), after several stretchings (C), after addition of epinephrine (EP), and after addition of $NaNO_2$ (NO_2).

In this "aging" process, as the aorta increases its capacity, the relative volume gain per unit pressure rise, as related to this initial capacity, is diminished. This change, the physicist would clearly term a decreased distensibility. Yet when the actual volume-pressure relations for all forty-eight aortas were plotted on the same figure, the most constant feature between them was the actual volume gain, without any reference to initial size. This relative constancy is fortuitous, for it is this actual volume increase that we wish to know when we would quantitate the pulse pressure in terms of volume. What a relatively stable actual volume increase, in face of the marked differences in relative distensibility, would mean to the physicist can hardly be treated in the time allotted. Individual variation away from the average net uptake figures averaged 25 to 30 per cent for the human series and 15 to 20 per cent for the dogs. Intrinsically, then, if we use these average values to predict actual volume uptakes from the pressure change in living individuals, we can hardly expect an accuracy greater than this. Actually, the error has often turned out to be less, as though the autopsy series contained an undue number of "atypical" aortas.

The cardiometer workers were not protesting the use of the pulse pressure as a measure of stroke volume between individuals, however. Where they had failed was in finding corresponding changes in pulse pressure when the stroke volume was acutely changed in the same dog. This implies that arterial distensibility shows physiological variation. The arteries have muscular walls. Even the aorta has variable amounts of smooth muscle. There is no reason to suppose that this muscle will not be influenced by nervous and humoral stimuli. MacWilliam, in 1902,[6] reported that when the aorta was first removed from the body, it was small and quite firm. After manipulation, it became larger and flabby. Stretch curves made on aortic segments in the two states showed that the firm aorta had a greater relative distensibility. The sort of changes he was observing can be illustrated by some recently recorded volume-pressure relations for a ring of dog ascending aorta, as shown in Figure 1. Upon first removal from the body (1st) the ring was small. After several stretchings, it was considerably larger. After the addition of epinephrine to the bathing medium, the ring again became contracted, while after $NaNO_2$ was added, it was relaxed. Just as was the case of the capacity changes in aging, however, the actual volume-pressure curves show a fairly good parallelism despite these tone changes. This means that an average volume uptake table can discount the effect of tone changes.

When Dr. Hamilton and I started on this problem, it seemed that the really major source of error had not even been considered. So far I have been speaking as though the only variable between pulses was the height of the pressure rise. Actually, in different circulatory conditions, the central pulse contour of the dog may take quite divergent forms, with the peak falling in early, mid or late systole, and the duration of ejection varying from 80 to 230 millisecond. The pulse pressure itself cannot be expected to signify these different contours. The volume uptake of the arterial bed should instead be related to the time-pressure area under the systolic portion of the pulse curve. But the problem is even more complex. The heart is ejecting into one end of a long network of tubes; all of which comprise the arterial receiving chamber. At the very first of systole, only the ascending aorta is accepting blood, and a given volume input must produce an inordinately large pressure rise. As the pulse wave moves out the vascular tree, the size of the reservoir is constantly increasing. Some means must be found to weight the parts of this time-pressure area for the progressive increase in reservoir size.

To evaluate the dimensions of the receiving chamber, we need the net volume increases per unit pressure rise, and the various pulse wave transmission times at different pressures, for the arterial beds. The former were assembled from evidence based on pressure rises following injections of known amounts of blood, or on tension-length curves obtained by stretching rings of vessels.[10] For the latter, transmission times were recorded to various arteries easily entered by manometer needles, and the values for other beds assembled by reasonable extrapolations. Next, all vessels lying the same time-distance from the heart were grouped together, to be treated as though they comprised a single tube. The different values for the volume uptakes of these vessels were also lumped by the same pattern. Hence we can know, for this single tube, the volume gain per unit pressure rise for each millisecond of its length. Now if we assume that a given central pressure pulse will pass through this theoretical tube without any change in form, we can calculate, moment by moment, the volume uptake of all parts of the tube, which can be summated for the total volume uptake.

This total uptake does not represent the stroke volume. As the pulse wave reaches the terminal arterioles, drainage is accelerated because of the increased pressure. The extra blood so lost must come from the reservoir, and rob it of some of its uptake. This drainage is estimated in a rather gross fashion. We assume that the outflow rate will be linearly proportional to pressure, less 20 mm. Hg, which is taken as the level at which flow ceases. This pressure level presumably is altered under different physiological conditions, but there are no convenient handles by which it can be corrected to meet the specific circumstance. Let us also say that all of the above determined uptake drains from the arterial reservoir during the succeeding diastole. Systolic drainage then can be calculated by the ratio of the time pressure areas under the systolic and diastolic parts of the pulse, multiplied by the uptake. Yet not all of systole is available for systolic drainage, for time is required for the pulse wave to reach the terminal arterioles. Transmission times to the various large drainage beds were obtained by extrapolations. Next, the fraction of the total cardiac output that normally flows through each bed was arbitrarily assigned, using values taken from the literature. The products of the flow fraction and the transmission time for all beds were summed, and averaged, to give a flow-weighted time value that we call Tw. This Tw then represents the mean time required for the pulse wave to reach an arteriole that carries an average amount of the total flow. This term Tw has a specific definition. The use of the symbol for times values differently derived can seemingly only lead to confusion.[13]

The effective systolic time for drainage can now be taken as the total systolic duration less Tw. Having calculated the total volume of systolic drainage, a fractionation between beds can be made, and the time course of systolic drainage determined. When the uptake and the drainage curves are summed, we should have the total ejection curve.

When we desire only the stroke volume rather than the ejection curve, the calculation need not be so elaborate. The whole stroke volume must be delivered at the time of the incisura, when the valves close. We should know the uptake values for the different regions of the composite tube at this moment. For simplicity, the tube is treated as composed of four segments only, each segment beginning its uptake when the pulse wave has reached the mid-point.[4] These half-times for each segment were tabulated. The pressure height for each segment, which should be proportional to end-systolic uptake, is obtained by laying back this time from the incisura on an actual pulse. The segment uptake for this pressure height can then be obtained from a table. When this process is repeated for each segment, we will have four uptake values which can be added for the total uptake.

The whole technique rests on the accuracy of transmission times, and the applicability of our set of average time values to different animals, or to different physiological conditions in the same animal. When we studied the arch-iliac transmission time for a number of animals at a given pressure level, we found the individual variations to be about 10 per cent of the mean. We were not able to establish any systematic deviation according to body size, indicating that such a trend was being masked by a larger variation attributable to tone changes and the other physiological factors which influence the wave velocity.[5] We therefore have no data to allow a correction for body size, nor can we safely speculate as to how these times would be affected when both wall thickness and vessel length are increased as the body becomes larger. As to the physiological variations, we have seen that when tone changes occur, they affect the relative distensibility, which conditions the pulse wave velocity much more seriously than the volume uptake values. It would seem safer to apply a standard set of transmission values than to make corrections every time the pulse wave velocity might change in a particular artery.

Alexander[1] did find a trend of arch-femoral transmission times according to body weight. When he calculated stroke volume with time values revised for each animal, the average difference between the values obtained and those given by our single table was some 6 per cent. The difference proved to be random rather than systematic. He concluded that the use of average time values had not introduced a really serious error, a belief we had had from the beginning.

We hear much of a lengthening, with the development of tortuosity, in the vessels in older humans. In our eighty-three aortas, length changes were certainly less clear than were changes in diameter, and individual variations not nearly so large. We should remember, also, that when age and/or hypertension produces such a lengthening, it also produces a thinning of the wall and a decreased relative distensibility. The resultant increased pulse wave velocity might easily compensate for the greater length.

The quantitative justification of the volume calculations, as outlined, requires a check with a recognized measure of cardiac output, done simultaneously. No other procedure, however, measures individual stroke volume, but rather gives a value for mean flow over a relatively long period of time. Since dog pulses may vary quite appreciably from beat to beat, the selection of single pulses which shall typify the whole time span is a problematical procedure. Making as reasonable guesses as possible as to pulse selection, the contour calculation has been compared with the Fick or the dye injection techniques in four different laboratories, and the results in three are fairly similar. The average disparity between the two procedures is from 10 to 15 per cent.[7] The results of some 400 such comparisons, done at Georgia, are shown in Figure 2. These points cover a wide range of experimental conditions, including both hypertension and hypotension, acute and chronic.

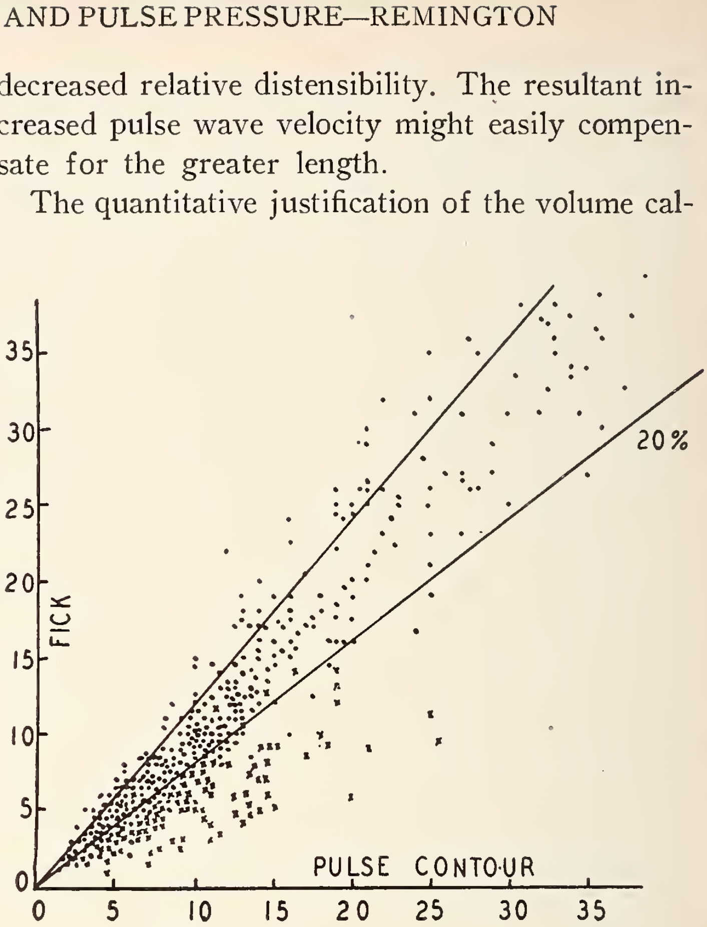

Fig. 2. A comparison of the stroke volumes obtained by the Fick procedure, using oxygen, and the Pulse Contonur calculations for 400 experimental cases in dogs. The lines represent a spread of ±20 per cent from the line of identity. For the difference between points and crosses, see text.

These points are fairly sharply divided into two clusters. The dots group around the line of identity without a systematic deviation. Seventy-three per cent of them lie within the limits of ± 20 per cent. These are from a great many different circulatory states in dogs in relatively good condition. The crosses, on the other hand, show a large number of poor fits with the Fick results, with the disagreement always in favor of an excessive pulse pressure for the corresponding stroke volume. The aberrant pulse contours tend to have a common form, with a very sharp anacrotic pressure rise, poorly sustained pressure in later systole, and a relatively brief duration of ejection.[8] These pulses come, in the main, from animals in what we might term a "normatensive" shock state—animals with but slightly subnormal pressure levels, suffering from only a mild blood volume reduction, but with cardiac output levels that can only lead to death. It is curious that as an open-chest dog deteriorates, it is prone to enter this peculiar state. Why the distensibility behavior of the arterial bed is changed so radically, and by what mechanism, is a most intriguing problem.

The fact that the pulse contour calculation is not applicable to all situations is of course disappointing. But we must not let this disappointment blind us to the fact that if we discard pulses of the aberrant form, and avoid conditions where such aberrancies might appear, the technique can yield a great deal of most profitable information.

In developing a case for the cardiometer workers, we have presented a number of points that could have sufficed to strengthen their case. However, we have also attempted to discredit each of them. The only good reason remaining for the reported lack of correlation was in the assumption that the pulse pressure could typify a pulse contour. It is interesting in this regard that when the method was applied to some records published long ago by Yandell Henderson, the calculated stroke volumes agreed quite well with those he obtained with a cardiometer.[9] Yet even this assumption should have allowed a recognizable trend between stroke volume and pressure change in the earlier work, unless enough of their experimental animals had entered the shock state. In addition, I am often reminded that the favorite device for adjusting the pressure level in their preparations was an occlusion of the aorta, which of course radically altered the size of the receiving chamber. Curiously enough, an increased pressure excursion, with relatively the same stroke volume, produced by such an occlusion seems to have been one of the crowning pieces of evidence that a relation between the two could never be expected.

How much of this methodology is applicable to the human? When we derived the dog technique, central pulse contours in the human were not being recorded. We did collect a series of brachial pulses, recorded directly from the artery at the same time that a Fick determination of cardiac output was being done. A large portion of these were borrowed from the files of Dr. Andre Cournand. With not a great deal of confidence in the results, we empirically constructed a pulse contour method for these pulses. The lack of confidence stemmed from the fact that these pulses often showed only a superficial resemblance to what we might expect of a central pulse, if a human resembled a dog. From the records I have seen in Dr. Wood's laboratory at the Mayo Clinic, this premonition seems to have been well founded. These brachial pulses usually did not show any remnant of the incisura, or even any constant landmark which could be taken as marking the end of systole. The brachial pressure values themselves were heightened to variable degrees by fusion with reflected waves. Curiously enough, despite these handicaps, the contour calculations gave an average fit of ± 20 per cent from the Fick value.[11]

If variability in the basic data were comparable, central human pulse contours would seem better suited to accurate volume predictions than are dog pulses. Changes in contour seem far less extreme, heart rates are much more stable, beat-to-beat variations in pressure much smaller, and the length of systole much longer and more stable than for the dog. The long systole minimizes the effect of the expansion of the arterial reservoir during systole. On the other hand, it increases the systolic drainage fraction of the calculated stroke volume. We have followed with considerable interest the efforts of the Mayo group to construct a contour method for the central pulse of man.[13]

Limited as we were to brachial pulse records, we doubted that the accuracy achieved by application of the contour calculation methods to an unsuitable pulse, was rewarding enough to continue the approach. We therefore returned to the original Erlanger and Hooker notion that the brachial pulse pressure, *per se*, could be quantitatively related to the stroke volume. As we have said, this implies a stereotype contour form.

From the pulse pressures and the known stroke volumes, we derived a set of volume factors

TABLE I. FACTORS FOR THE PREDICTION OF STROKE VOLUME, PER SQ. M. BODY SURFACE, FROM THE PULSE PRESSURE

Pressure	Volume Factor	Pressure	Volume Factor	Pressure	Volume Factor
mm. Hg.	cc.	mm. Hg.	cc.	mm. Hg.	cc.
20	0	100	81	180	140
30	10	110	90	200	148
40	21	120	100	220	155
50	31	130	108	240	161
60	42	140	115	260	167
70	52	150	122	280	173
80	62	160	128	300	179
90	71	170	134		

(Table 1), corrected for body size and for the inflections in the aortic distensibility curve. If, for example, the brachial pulse pressure was 120/80, then the predicted stroke index, from Table I, would be 100-62, or 38 cc. As a rule of thumb, over the usual pressure range, 1 mm. Hg, pressure rise is about equivalent to 1 cc. stroke volume/sq. M. body surface. The average error of these predictions was about 25 per cent. How good a fit this is depends upon one's viewpoint. If workers with the ballistocardiogram got such an agreement, they would be quite content. For the experimental investigator it leaves much to be desired.

For the diagnostician, a prediction with this error should still furnish a great deal of useful information as to the direction and general magnitude of cardiac output changes. After all, the flow changes with which he is most concerned tend to be larger than the intrinsic error. In case of critical, or small, changes in flow, corroborative support from a direct cardiac output determination would, of course, be necessary.

DIAGNOSTIC PROCEDURES IN DETERMINING CONGENITAL CARDIAC DEFECTS

Aside from a thorough history and physical examination, the most important single diagnostic procedure which can be done in the physician's office is careful fluoroscopic examination. A good deal will be missed if the fluoroscopy does not include the right and left anterior oblique views in addition to the usual posterior-anterior view. Fluoroscopy will demonstrate enlargement of the individual cardiac chambers and will give information as to the contour and activity of the pulmonary vessels.

The electrocardiogram, especially with precordial leads, is useful in demonstrating ventricular hypertrophy. Right axis deviation is found in the tetralogy of Fallot, left axis deviation in tricuspid atresia.

Catheterization of the heart may be helpful in a difficult case. A special catheter is inserted into an arm or leg vein and gently advanced under fluoroscopic visualization to the right auricle. The catheter is then passed through the valve into the right ventricle and, usually, into the pulmonary artery.

In the case of an over-riding aorta, the catheter may be passed from the right ventricle directly into the aorta. It is sometimes possible to pass a catheter through an auricular or ventricular septal defect. Blood samples are taken from the different chambers and analyzed for oxygen content. Information may thus be obtained concerning left-to-right shunts, such as patent ductus, by analysis of the oxygen content of blood samples drawn from the right ventricle and pulmonary artery. (The latter sample will have a greater oxygen content because of the flow of oxygenated blood from the aorta.) The presence of auricular and ventricular septal defects will similarly be demonstrated. By a manometer attachment to the catheter a recording of pressures during systole and diastole is made. This is helpful in showing the presence of pulmonary stenosis when a recording of the pressures in the right ventricle is high and in the pulmonary artery is low.

Catheterization must be carried out by a well-trained team in a hospital, and usually general anesthesia is necessary.

Angiocardiography is a procedure in which a radio-opaque dye is injected into a vein and with a special camera x-ray films of the heart are taken in rapid sequence. These films visualize the great vessels and individual chambers of the heart as they are filled by the dye.

Angiocardiography is particularly useful in the diagnosis of defects such as coarctation of the aorta. It may be of some help in the diagnosis of transposition, truncus arteriosus, tricuspid atresia and anomalous venous drainage. In an older, co-operative child, it may be carried out without anesthesia.

QUANTITATION OF STROKE VOLUME CHANGES IN MAN FROM THE CENTRAL PRESSURE PULSE

HOMER R. WARNER, M.D., Ph.D.
Salt Lake City, Utah

IN the preceding paper Dr. John Remington has given us an historical background to the problem of estimation of left ventricular stroke volume from an arterial pressure pulse. He has also presented some of his own work in this field, and has pointed out some of the difficulties he encountered in trying to apply this method to the study of man. I should like to present briefly a somewhat different approach to the problem. The work I shall describe was carried out in conjunction with Dr. Earl Wood, and others in the physiology laboratory of the Mayo Clinic.[4]

The pressure wave generated in the aorta and large arteries by the periodic ejection of blood into this system by the left ventricle is a complex phenomenon. Necessarily, in any attempt at the present time to quantitate volume changes, from a recording of this pressure pulse, must be considered only a first approximation, and the attempt is justified only if the results obtained possess a useful degree of accuracy, and if the attempt suggests new and more precise means of approaching the problem.

Inasmuch as the pressure wave traverses the arterial system with a finite velocity, pressure in this system is a function of at least two variables, namely, time in the cardiac cycle (T), and distance down the arterial bed (X). Pressure can be recorded as a function of time at a fixed point in the system. If a plot of pressure as a function of distance at certain specified time, could be obtained, namely the onset of systole and the end of systole, the difference between the mean pressures over the length of the system at these two instants would be the pressure change corresponding to the volume change which Dr. Remington has named the systolic uptake—that is, the volume of the arterial bed at the end of systole minus its volume at the onset of systole.

In order to calculate (P) as a function of (X) from a record of (P) as a function of (T), one must know (X) as a function of (T). The first derivative of this relationship $\frac{(dx)}{(dt)}$ is the pulse wave velocity, and this has been found to be an increasing non-linear function of (X), and varies considerably from one individual to the next. However, it was found that changes in mean pulse wave velocity between two points in the arterial bed (for instance between the brachial and the radial artery) are proportional to changes in mean velocity between any other two sites (aortic arch to femoral artery for instance). Thus changes in pulse wave velocity between two recording sites in the arterial bed can serve as an index to the time of transmission of the pulse wave down the whole system (Dr. Remington's Tw).[2]

The length of that portion of the arterial bed that acts primarily as a passive elastic chamber is arbitrarily assigned a value of 60 cm. Then on the basis of an average pulse wave velocity in the resting supine subject of 6 meters/sec. in this segment, transmission time over the length of the system (Tw) would be 100 milliseconds at rest. A proportionality factor, between this and the measured transmission time at rest, between the two recording sites, is then calculated and used to estimate subsequent values for Tw in that individual. The accuracy of the resting, assumed value for Tw is not at all critical to value for stroke volume obtained by this method, since only changes in stroke volume are to be calculated.

In Figure 1 is shown a pressure-time record recorded through a small catheter, the tip of which lay in the aorta, and another, whose tip lay in the femoral artery. The integrated mean pressure between the limits of the onset of systole on the central pulse and a point Tw back from this point, serves as an index to the mean pressure down the aorta and large arteries at this instant. The difference between the mean pressures down the system at the onset, and the end of

---

systole, is the pressure increment which we have called the mean distending pressure, and which corresponds to the volume change—systolic uptake.

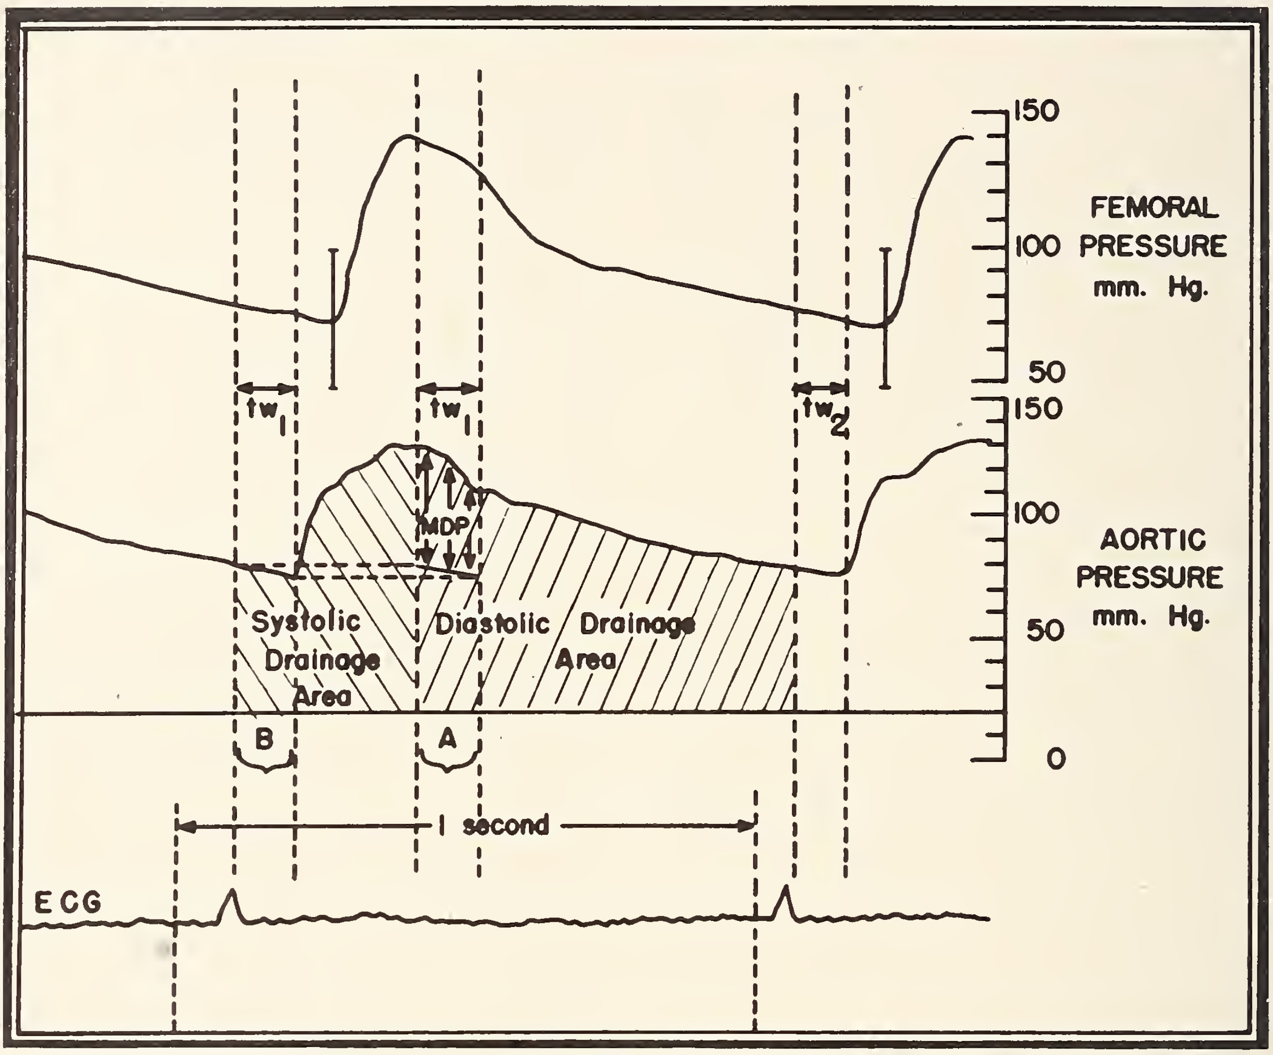

Fig. 1.

of this, a linear relationship between volume and pressure is used as an approximation in the method being described.

The other measurement to be made from the pressure record is also shown in this figure, namely, the ratio of the systolic to the diastolic time-pressure integral above 20 mm. Hg, corrected for the delay in transmission of the pressure wave to the periphery.

Dr. Remington has shown a plot of the volume-pressure relationships which they obtained by stretching rings of aorta from recently dead humans.[3] They found a marked individual variation in size and distensibility within any given age group. Although not evident in their plot of average values, examination of the individual values shows considerable variation in slope from one individual to the next. As a matter of fact, the data would indicate that the variation from linearity, when it occurs, is relatively small in comparison to the individual variation. Because

In order to arrive at this proportionality factor relating change in pressure to change in volume for a given individual, cardiac output is measured with the subject at rest by an independent method (either the Fick or the dye method) while the pressure pulse is being recorded. Systolic and diastolic time-pressure integrals and mean distending pressure are measured, from each pulse during the independent cardiac output measurement, and averaged.

A sample calculation, that illustrates the application of these equations to the measurement of changes in stroke volume produced by exercise, will clarify the preceding paragraphs.

Person at rest:
Pmd = 39 mm. Hg (measured value)
Sa/Da = 0.48 (measured value)
SV (dye) = 127 cc. (measured value)

Equation 8:

$$SV = U + \frac{Sa}{Da}U$$

$$127 = U + 0.48U$$

$$U = \frac{127}{1.48} = 86 \text{ cc.}$$

Equation 4:

$$k = \frac{U}{Pmd} = \frac{86}{39} = 2.21 \text{ (to be used in subsequent determinations).}$$

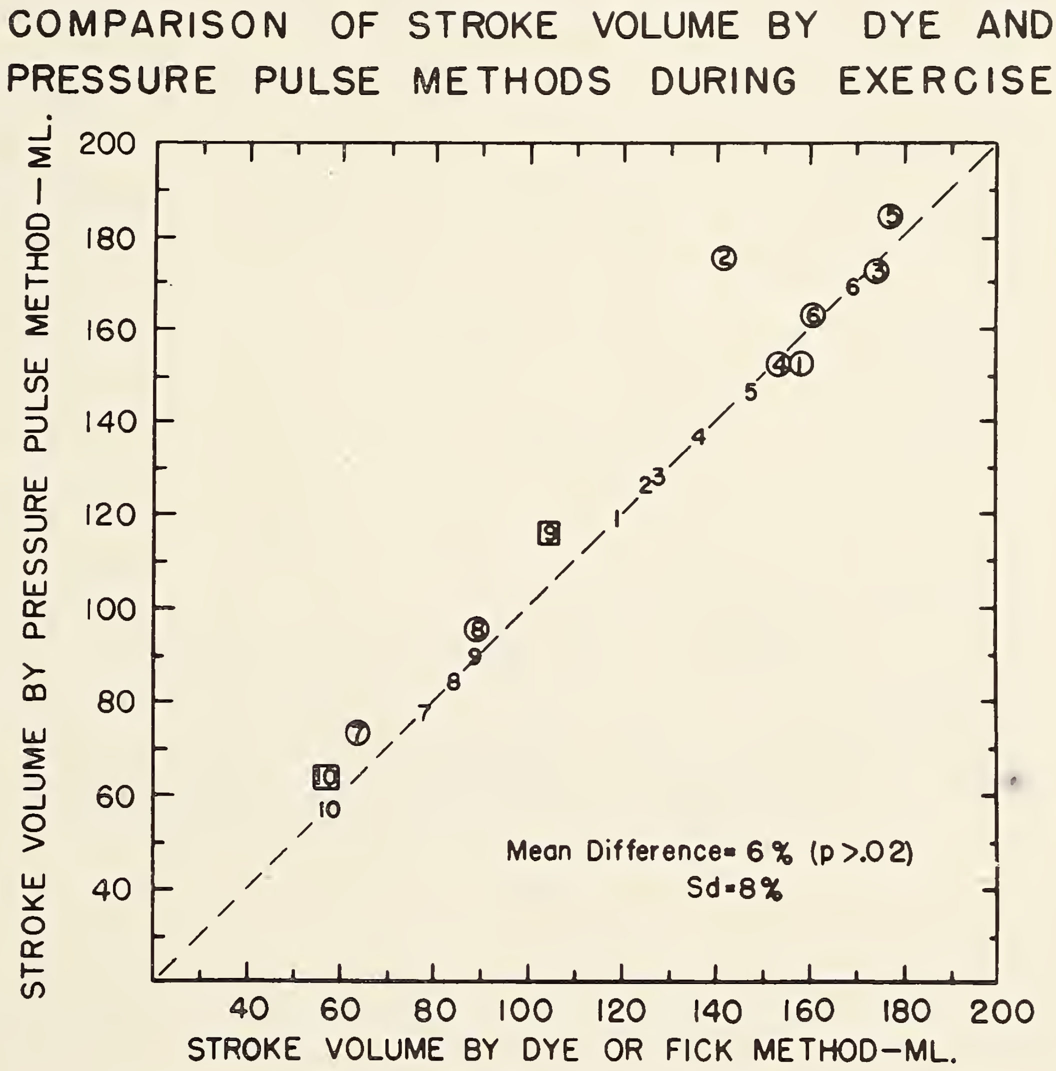

Fig. 2.

Person exercising:

$Pmd = 41$ mm. Hg (measured value)

$Sa/Da = 0.93$ (measured value)

Equation 9:

$$SV = kPmd\left[1 + \frac{Sa}{Da}\right]$$

$$= 2.21 \cdot 41\ (1 + 0.93)$$

$$= 174 \text{ cc.}$$

SV (dye) = 179 cc. (measured value).

Before showing the results of comparisons of this method with the Fick and dye method, I should like to describe briefly the techniques employed and some of the precautions taken to insure a faithful recording of pressure. Central arterial pressure-time records were obtained through a small plastic catheter[1] 0.5 min. interval diameter advanced either into a subclavian artery, through a thin-walled 18-gauge needle in a brachial artery, or into the aortic arch by way of a needle in a femoral artery. The proximal end of the catheter was attached to a three-way stopcock which allowed alternate recording with a strain gauge and a capacitance (Lilly type) manometer. The output of the manometers was fed into d'Arsenval type galvanometers and recorded photographically using a two meter light arm. This alternate recording arrangement was used to test the minimum response characteristics necessary to record a central arterial pressure pulse.[5]

After withdrawing the catheter at the conclusion of each experiment, the tip was placed in a low frequency oscillator chamber and the response of the system to square wave and sine wave pressure variations of varying frequency was tested. The strain gauge system was almost optimally damped with its peak response at 15 cps while the capacitance manometer was underdamped, overshooting 700 per cent at its peak frequency of 90 cps.

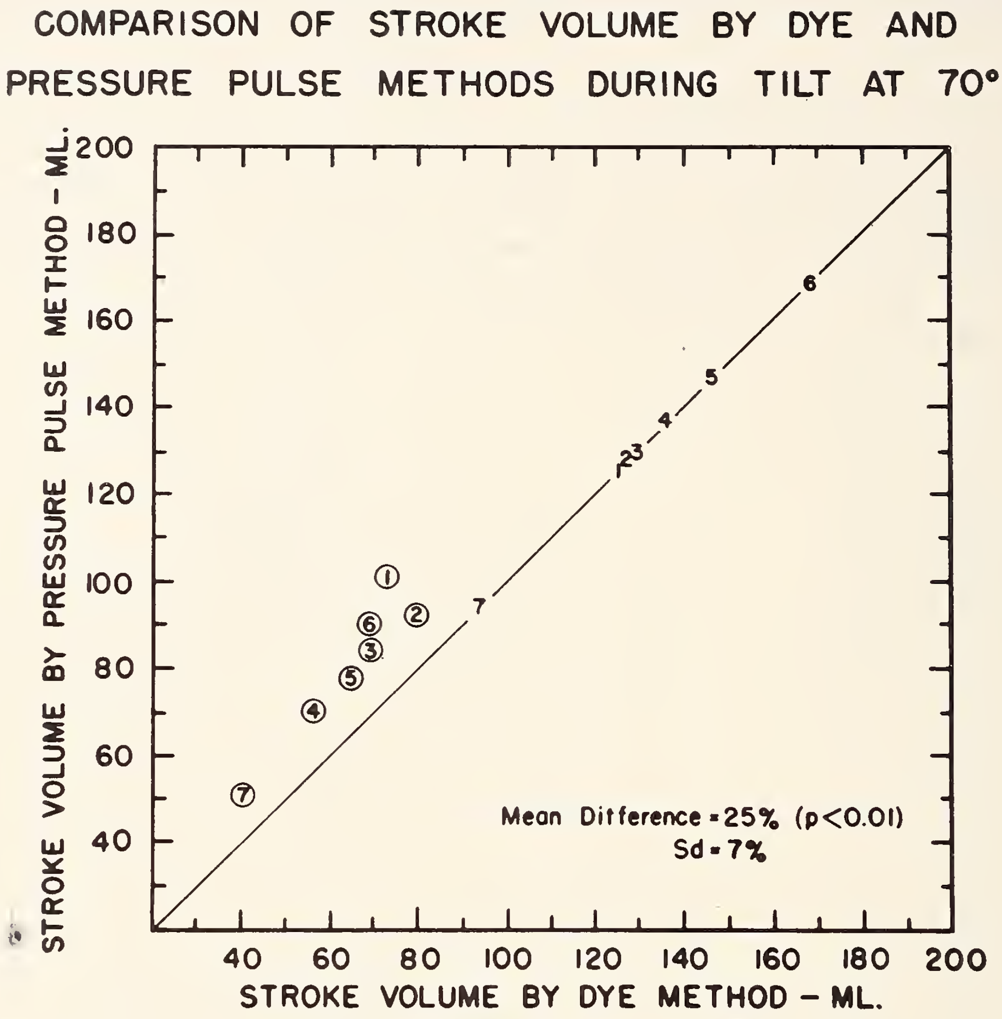

Fig. 3.

A comparison was made of aortic pressure pulses recorded by the strain gauge and the capacitance manometer-catheter systems. It is of interest that the vibrations observed, just preceding the onset of systole, and at the anacrotic and dicrotic notches, were of the resonant frequency of the catheter-manometer system, and thus do not represent actual pressure variations within the arterial system. No measurable difference in the pulse recorded by the two systems was found except in the time delay in onset as measured from the R wave of the electrocardiogram. The calculations made in the present study were carried out on recordings made with the strain gauge manometer. Because of the stability of this instrument, it was considered the manometer of choice for this type of study. Femoral artery pressure was recorded through a short catheter and right brachial and right radial artery pressure through indwelling needles. Dye concentration in arterial blood was recorded continuously with a curvette oximeter and an ear piece oximeter. Curves of dye concentration were recorded at a camera speed of 5 mm/sec. while the pressure pulses were recorded simultaneously with another camera at a speed of 80 mm/sec. In this method I have just described a record of a central and only one peripheral pulse is required.

Figure 2 shows a comparison of stroke volume by the dye or Fick and the pressure pulse methods during exercise and includes data from six normal subjects and four patients with mitral stenosis. The uncircled numbers on the line of identity are the resting values and are shown only to demonstrate the magnitude of the change in stroke volume that occurred during exercise. The circles are comparisons made during exercise with the dye method and the squares with the Fick method. In this series the mean stroke volume increased only 11 per cent, but the average exercise cardiac output was 182 per cent of the resting value and heart rate increased thirty-five beats per minute. The mean difference between the values obtained by the pressure pulse, and the control method was 6 per cent and the standard deviation of the differences was 8 per cent.

Figure 3 shows a comparison of stroke volume by the pressure pulse and the dye method carried out four to five minutes after tilting the subject to head up position, 70° from the horizontal. Under these circumstances a significant systemic difference was observed, but the standard deviation about this difference was small, being only 7 per cent. In the tilt position, stroke volume averaged 61 per cent of the resting value by the pressure pulse method, and 53 per cent by the dye method. The reason for the systematic difference in the tilted position is not clear as yet.

In Figure 4 are shown twelve comparisons of values for stroke volume obtained by the Fick and pressure pulse methods under a variety of physiologic conditions, including tilt to various positions and inflation of a new type antiblackout suit which applies 75 mm. Hg pressure to the entire body below the xyphoid. Under these circumstances no systematic difference was obtained and the standard deviation of the differences was 10 per cent. In this series of observations, mean arterial pressure varied from 81 to 149 mm. Hg, and heart rate from 84 to 125 beats/mm., providing a rather rigid test of the ability of the method to follow stroke volume changes under conditions producing marked alterations in the status of the cardiovascular system.

In conclusion, a method for estimation of stroke volume in man from a recording of a central and a peripheral pressure pulse has been presented. This requires the obtaining of a factor relating change in arterial pressure to change in volume, by carrying out a determination of stroke volume during a steady state period by an independent method. Inasmuch as the usefulness of a pressure pulse method lies primarily in its ability to follow rapid changes in stroke volume, this would not appear to be a serious disadvantage. Basically this approach differs from

CARDIAC CATHETERIZATION IN DIAGNOSIS OF CONGENITAL HEART DISEASE

LEWIS DEXTER, M.D.
Boston, Massachusetts

NOTABLE IMPROVEMENT in the diagnosis of congenital heart disease has been achieved as a result of the introduction of cardiac catheterization. The purpose of this communication is to point out information that can be obtained by this procedure as well as to indicate its shortcomings. Catheterization may provide useful data by the following means: (1) the demonstration fluoroscopically of the *introduction of the catheter* into an *abnormal pathway;* (2) the demonstration of an abnormal pressure gradient across the pulmonic or tricuspid valve, indicative of stenosis of the valve; (3) the demonstration of the identity of the systolic pressures in the right ventricle and brachial artery, indicative of an overriding aorta or a functionally similar condition; (4) the demonstration of the presence of arterialized blood in one of the chambers of the right side of the heart or in the pulmonary artery, indicative of a left-to-right shunt; and (5) the demonstration of arterial oxygen unsaturation not corrected by the administration of 100 per cent oxygen of a right-to-left shunt. The latter procedure does not involve catheterization, but is often carried out in conjunction with it.

In addition, the determination of flows, pressures, and resistances at rest and during various physiological stresses, permit a better appreciation of the abnormal physiological processes and a deeper insight into the clinical course and natural history of the disease.

1. *Introduction of catheter into or through abnormal pathways.*—This is one of the most reliable ways of diagnosing a congenital heart lesion if the abnormal pathway can be definitely identified. Catheters have been passed through or into the patent ductus arteriosus, aortic septal defects, atrial septal defects, anomalous pulmonary veins, ventricular septal defects, overriding aortas, double superior vena cavas and others. It is usually not difficult to determine the catheter's exact position with the aid of oblique and lateral as well as anterioposterior fluoroscopy. In my opinion it is, however, extremely difficult, if not impossible, to differentiate an anomalous pulmonary vein from an atrial defect, as the course pursued by the catheter may be very similar.

2. *Abnormal pressure gradient across a valve.*—There is normally no more than 1 to 2 mm. Hg difference in pressures between the right auricle and right ventricle during the first fraction of a second of diastole, or between the right ventricle and pulmonary artery, during systole. The most accurate and sensitive indication of stenosis of the tricuspid or pulmonic valve is the demonstration of a significant pressure gradient across the valve. Until 1946, only about seventy cases of pure pulmonic stenosis were described pathologically in the medical literature. Since the advent of physiological measurements, enabling pressures to be recorded on both sides of the valve, many hundreds of cases have been recognized. Pulmonic stenosis may now be considered to be one of the most common of congenital defects. I hope Dr. Bing will describe the manner in which the valvular type stenosis can be differentiated from the infundibular type by means of a cardiac catheter.

3. *Identical systolic pressure in right ventricle and brachial artery.*—With dextroposition or overriding of the aorta, the aorta and right and left ventricles are in direct communication during systole. With minimal overriding, there may be a difference in systolic pressures of the right ventricle and aorta. When free communication is present, however, the pressures are essentially the same *under all circumstances.* Brachial arterial pressure tracings in the adult have been found to be more representative of aortic pressure than femoral or radial artery recordings. In all but one of our cases with established overriding, identical brachial arterial and right ventricular systolic pressures have been demonstrated. The

---

Presented in the Symposium on Recent Advances in Cardiovascular Physiology and Surgery, University of Minnesota, Minneapolis, September 15, 1953.

This work was supported by grants from the Life Insurance Medical Research Fund and the U. S. Public Health Service (H-450).

one exception had a brachial arterial pressure 20 mm. Hg lower than the right ventricular pressure; this was perhaps due to an anomaly of the arteries supplying the upper extremity.

Identical systolic pressures in the right ventricle and the aorta are also present in large intraventricular septal defects, cor triocular biatrium, and common truncus arteriosus. In these conditions, there is no anatomical overriding of the aorta, but there is free communication between the right and left ventricles and the aorta during systole. Thus identity of systolic pressures in the right ventricle and brachial artery is found in lesions with a wide anatomic variation but with a common physiological behavior.

In primary pulmonary vascular disease, or when pulmonary vascular complications have developed in mitral stenosis, ventricular or atrial septal defects, or patent ductus arteriosus, the right ventricular systolic pressure may be elevated to systemic levels and be identical with that of the brachial artery at rest. Our experience indicates the identity of such pressures to be more than mere coincidence. This group of lesions can readily be differentiated from those with free communication between right ventricle and aorta by altering the pressures with exercise or by the administration of hypertensive or hypotensive agents. In those with a free communication between right ventricle and aorta, pressures in both areas rise and fall together, whereas in the second group, the systolic pressure in the right ventricle and/or pulmonary artery rises on exercise much higher than that in the brachial artery.

4. *Left-to-right shunts.*—Left-to-right shunts can be recognized by noting the appearance of arterialized blood, that is, blood high in oxygen content, in the pulmonary artery, right ventricle, or right auricle. The interpretation of this may not be simple. For example, the presence of arterialized blood in the pulmonary artery may signify any of the following: (a) patent ductus arteriosus, (b) aortic septal defect, (c) blood aspirated from the pulmonary capillaries and veins. The latter occurs only when the catheter is wedged into a terminal branch of the pulmonary artery, and thus should not lead to the erroneous interpretation that a shunt is present. Differentiation between the first two, however, is impossible by determining the oxygen contents of pulmonary arterial blood samples.

The appearance of arterialized blood in the right ventricle indicates either: (a) ventricular septal defect, or (b) patent ductus arteriosus with pulmonic insufficiency. Usually there is no difficulty distinguishing the two by clinical means unless both defects co-exist.

Arterialized blood in the right auricle may be due to: (a) atrial septal defect, (b) anomalous pulmonary vein entering the right auricle, (c) ventricular septal defect with tricuspid insufficiency, (d) common auriculoventricular valve with shunt from left ventricle to right auricle, and (e) ? coronary auriculoventricular aneurysm. With the exception of ventricular septal defect with triscuspid insufficiency these lesions cannot be accurately differentiated from one another by cardiac catheterization. I am not sure that a coronary auriculoventricular aneurysm provides a sufficient amount of oxygenated blood to raise the oxygen content in the right auricle sufficiently to be recognized. An elevated oxygen saturation of blood withdrawn from the coronary sinus should be diagnostic. Atrial septal defect, is by far the most common of the lesions listed, and it is for this reason that this diagnosis is often made so dogmatically. I am a sinner in this regard. Actually, the above differential always exists.

Thus, abnormal physiology can be translated to abnormal anatomy only as an approximation. The precise location of the defect in the atrial, or ventricular septum, cannot be determined. The size of only the smaller defects, wherein there is a pressure gradient across them, can be calculated. The larger ones can easily be recognized, but it cannot be ascertained if it is a defect of 3 cm.^{2}, or one in which there is no septum, or only an irregular peripheral rim. These points are of extreme importance to the surgeon, but cannot be answered by cardiac catheterization.

The magnitude of the shunt can be calculated using the Fick principle. I agree with Dr. Stow and Dr. Visscher that the Fick output, under the most ideal conditions, lacks precision, and that when shunt flows in congenital heart diseases are calculated, the errors may be great. It was with considerable hesitation that we originally made such calculations, and at best they may afford only crude approximations. The figures are at times so grossly in error as to be ridiculous. We have studied two patients with presumable atrial septal defect in whom the oxygen content of the pulmonary arterial blood was the same as that taken from the brachial artery. The pulmonary

MEDICAL LIBRARY - UNIVERSITY OF MARYLAND

blood flow, as calculated by the Fick principle, was infinite. Our most recent case had a calculated pulmonary blood flow of 70 liters per minute. Obviously the error in calculation was so great as to be meaningless, except that it indicated a large shunt.

As discussed previously, the main errors stem from the presence of extremely narrow arteriovenous oxygen differences, and the difficulty of obtaining representative mixed venous blood samples. Depending on the reliability of these two factors, the calculation of flows, shunts, resistances, and cardiac work may or may not be justified.

Not infrequently young patients are seen with a congenital murmur, but with no disability except for cardiac anxiety of iatrogenic origin. Cardiac catheterization, satisfactorily performed, fails to detect abnormalities of pressure, oxygen content of blood samples, or calculated flow. Two possibilities exist to explain the murmur—either that there is a lesion in the left side of the heart, for example, subaortic stenosis, or that there is one in the right side of the heart which is too small to be detected by this technique. If, on consideration of all information available, the latter possibility appears to be the answer, one can then reassure the patient that the lesion, no matter what it may be, is of no clinical significance, whatsoever, and that he may consider himself to have in essence a normal heart. There is one reservation that must always be added, that is the potential vulnerability to subacute bacterial endocarditis. Of all lesions under these circumstances, the one most easily escaping detection is a small ventricular septal defect. Although small atrial septal defects are undoubtedly undetected more frequently than any other lesion, by the time they produce a murmur, their detection is usually straightforward.

5. *Right-to-left shunts.*—In general, angiocardiography is a much more valuable method for identification and delineation of right-to-left shunts than cardiac catheterization. Right-to-left shunts are recognized by the failure of arterial blood to become fully saturated upon the administration of 100 per cent oxygen. However, the location of the right-to-left shunt cannot be determined by this method, although this can often, but not always, be accurately deduced by noting that a given chamber of the right side of the heart has a higher pressure than the corresponding chamber of the left side. Actually such studies are poor in the precise information they give, and have been greatly improved by the ether test of Soulié, and especially by the dye injection technique of Wood, which will be discussed by Dr. Swan in the next communication.

6. *Understanding of abnormal physiology.*—Perhaps the most important contribution of cardiac catheterization to congenital heart disease, is the knowledge that is being acquired with regard to the pathological physiology of the circulation in the different types of lesions. In the past, congenital heart disease has been studied mainly from the anatomical and embryological points of view. The physiology and clinical aspects are currently under intensive study. As corrective surgery becomes more and more applicable to the various lesions, such studies will increase. There are now considerable gaps between the anatomical, physiological, and clinical interrelationships of the various congenital lesions. These must, and will be, filled in in the years to come. What, for example, is the clinical course of patients with atrial septal defect? I do not know the answer clinically or physiologically. Cardiac catheterization, with all its handicaps and limitations, serves as the single most important physiological tool of approximate diagnosis and investigation. Other physiologic tools must be added to bridge some of the many gaps that exist in our knowledge of these diseases.

Boston 15, Massachusetts

Discussion

Dr. R. J. Bing, Baltimore, Md.: I would like to comment briefly on two problems. One, the relative diagnostic value of special tests as compared to clinical procedures, and secondly, some of the problems of pulmonic stenosis with particular reference to its surgical correction.

There has been a great deal of discussion on the relative value of clinical methods, versus special tests in congenital heart disease. Most of us agree, that in a great majority of patients with congenital malformations of the heart, a diagnosis can be made by clinical means. I use the term "clinical" very loosely, because it comprises not only the history and physical examination, but also electrocardiography and fluoroscopy.

Special tests are catheterization of the heart and angiocardiography. I would like to mention here some of the specially helpful points in the clinical diagnosis of congenital heart disease. As to history: repeated respiratory infections suggest the presence of increased pulmonary blood flow and/or pulmonary hypertension; anoxic convulsions are in line with a marked diminution in pulmonary flow, and hemoptyses suggest pulmonary hypertension. If a non-cyanotic child is reported to be dyspneic on slight exertion, the possibility of isolated valvular pulmonary stenosis must be entertained.

The most important point, as regards to physical examination, is absence or presence of cyanosis. If cyanosis is present, then a right-to-left shunt exists. But since a right-to-left shunt can exist in patients who have diminished pulmonary artery pressure, and in those in whom it is elevated, other physical signs of diminished or increased pulmonary pressure and flow must be looked for. Thus, a marked accentuation of the second pulmonic sound points toward pulmonary hypertension. The location and character of the murmur, although not as important as in acquired heart disease, may give valuable information. If a systolic murmur is present in a non-cyanotic child, high in the second intercostal space to the left of the sternum, a valvular pulmonic stenosis may be the underlying malformation. Absence of a murmur in a severely cyanosed child suggests pulmonary atresia.

It may be seen from these isolated examples, that a good deal of information may be gained from conventional methods. Add to this the information gained from electrocardiography, and particularly from fluoroscopy, and it is little wonder that one is often able to arrive at a correct diagnosis by conventional methods alone.

Why, we must ask ourselves, do we then in many cases resort to the difficult procedures of catheterization and angiocardiography? Is it that in complicated malformations, clinical examination is not sufficient? This we believe not to be correct. It has many times been our experience that the diagnosis of complicated malformations has been made more difficult by catheterization and angiocardiography. Exact location of the catheter tip in the heart, is often debatable in these patients, or the contrast material may have entered a portion of the heart which cannot be accurately defined. On the other hand, special tests are often essential in diagnosing the more common malformations of the heart, particularly if there is overlapping of signs and symptoms. This is particularly the case in the non-cyanotic group. Frequently the differential diagnosis between auricular, ventricular septal defect, or patent ductus arteriosus is difficult without catheterization, particularly in the absence of typical murmurs. In the cyanotic group it may be difficult to differentiate a tetralogy of Fallot with large collateral circulation from an Eisenmenger's Complex or true truncus.

I would like to say a few words about the problem of pulmonic stenosis. Anatomically, it is not an isolated malformation, rather the type of associated malformation that influences the physiologic pattern, and therefore the surgical correction of the stenosis.

When pulmonary stenosis is associated with a ventricular septal defect, the stenosis is usually of the infundibular type. In the presence of an auricular defect, the stenosis is usually at the pulmonic valve. If there stenosis is usually at the pulmonic valve too. When is neither auricular nor ventricular septal defect, the there is overriding of the aorta, such as in the tetralogy of Fallot, the infundibular type is frequently found in the tetralogy of Fallot.

In infundibular stenosis, the subpulmonary tract is bounded by the right ventricular muscle, by the ventricular septum and by a muscle which separates the tract from the ventricular septal defect. This latter muscle is the crista supraventricularis. This subpulmonary tract may at times be very narrow and it is believed by some, including Blalock, that this subpulmonary tract is the primary source of obstruction in the infundibular type. Brock, on the other hand, while admitting that the infundibular tract is often hypoplastic, maintains that as a rule an effective lumen is adequate, and that the actual stenosis occurs at one level and is linear and diaphragmatic.

This difference in interpretation is of considerable surgical treatment. If the subpulmonary tract has an effective lumen and if the stenosis is linear, infundibulotomy may be practical; if the stenosis is a long narrow channel, this procedure is hardly adequate, and even infundibular resection may be difficult.

We examined this question by means of drawings and wax casts, which were prepared by pouring parafin into the cardiac chambers and thus obtaining a mold of the cardiac cavities. By means of these casts and drawings, we could show the reverted funnel-shaped entrance into the subpulmonary tract of the right ventricle, and we were also able to show that in addition to the narrowing of this tract resulting from hypertrophy of the muscle of its posterior wall producing "muscular stenosis;" there is also a secondary stenosis or "fibrous stenosis" which is linear and diaphragmatic and which is composed of fibrous rather than muscular tissue. It is our opinion that the fibrous stenosis results in very little additional narrowing of the internal diameter of the subpulmonary tract. Therefore, infundibular resection is the only direct surgical approach; whether this is able to overcome the obstacles, by removing a mass of muscular tissue of the subpulmonary tract, is still a very controversial question.

In valvular pulmonic stenosis, the morbid anatomy is very different, as has been shown by Edwards et al. Although there is often muscular hypertrophy, this does not result in narrowing of the right ventricular outflow tract. It is not surprising, therefore, that valvolotomy is the operation of choice in this malformation.

The physiopathology of these malformations have been described in great detail, and Dr. Dexter has mentioned most of the essential features. I want to mention only the physiologic and surgical importance of the degree of overriding of the aorta, in the surgical correction of pulmonic stenosis. It has been shown that most patients in whom the aorta overrides more than 50 per cent, died, during or shortly after construction of an artificial ductus, from acute pulmonary edema or severe pulmonary congestion. On the other hand, if there is no overriding, the construction of an artificial ductus results in right sided failure. The reason for this is that when there is marked overriding, the increased volume of blood reaching the left ventricle from the lungs, often this construction of the ductus has no escape. In the presence of pulmonic stenosis and an auricular defect, where there is no overriding, the construction of an artificial ductus leads to right side failure because increased return of blood into the left auricle will raise the left auricular pressure, and by tending to equalize the gradients between right and left auricle, diminish the right-to-left shunt. The subsequent increase in right auricular pressure leads to failure. Special tests have contributed very little to the recognition of the degree of overriding of the aorta. However, in Sweden, the use of regional angiocardiography has shown the way.

Physiologic tests have been particularly useful in the interpretation of operative procedures for pulmonic stenosis. In the tetralogy of Fallot, the construction of an artificial ductus produces a postoperative rise in the oxygen content of right ventricular blood. This may be due to increased inter-cardiac left to right shunting. This increased left to right shunt may also be responsible for the elevation of the right ventricular pressure which was observed in many patients.

In the treatment of isolated pulmonic stenosis with auricular defect, a condition in which valvolotomy is the method of choice, there is a fall in right ventricular pressure, which, however, never returns to normal; the pulmonary blood flow increases and the peripheral oxygen saturation rises.

Physiologic data obtained before and after infundibular resection in the tetralogy of Fallot are still scarce. However, Bailey and Glover used the infundibular resection in forty-two patients with the tetralogy of Fallot; of these twenty-two had infundibular stenosis. In patients who were catheterized postoperatively, the gradient between the systolic pressure in the right ventricle and the pulmonary artery was still very marked; the clinical results on the other hand, were far more satisfactory than one might expect from these physiologic data. It is hoped that future physiologic studies will justify some of the optimism evoked by these clinical observations.

Dr. H. B. Burchell, Rochester, Minn.: In respect to the general principles outlined by Dr. Dexter pertaining to cardiac catheterization and its diagnostic application, I am in agreement, although there are a number of small points about which I have somewhat different opinions. I can re-emphasize the difficulty in the differentiation of atrial septal defect and anomalous pulmonary venous connection (drainage) into the right atrium. Actually, no true differentiation can be made when the posterior segment of the atrial septum is missing.

I should like to reiterate the diagnostic value of exercise, not only for patients who have ventricular septal defect, but also for persons who have pulmonary stenosis. The obstructive nature of pulmonary stenosis, with an intact ventricular septum is often dramatically portrayed after exercise, when the right ventricular pressure may be increased much further while the cardiac output is insignificantly increased. Like Dr. Dexter, I consider that similarity of right ventricular systolic and systemic systolic pressures, particularly when this pressure relationship persists with exercise, is a strong indication of a large ventricular septal defect. It is important to remember, however, that the actual values need not be identical; systolic pressures in the radial artery that are 10 to 25 mm. of mercury in excess of the right ventricular systolic pressure can be regarded as "physiologically" identical. While in general it is considered that the right ventricular systolic pressure is correlated with the size of the ventricular septal defect, exact correlations in this regard are not available.

Dr. Dexter mentioned that breathing 100 per cent oxygen would differentiate cyanosis due to an intracardiac shunt from that due to pulmonary disease. It is important to recognize, that exceptions to this conclusion occur in that a right-to-left shunt, that is present when the patient is breathing air, may disappear when the patient breathes 100 per cent oxygen. This is thought to be related to a decrease in pulmonary resistance. A number of such instances have been encountered in which right-to-left shunts are demonstrable by dye techniques when the patient breathes air but which disappear when 100 per cent oxygen is used. In such cases the arterial oxygen saturation may be 100 per cent and the blood may carry its normal complement of dissolved oxygen. Previous papers in this symposium have pointed out the potential errors in the determination of pulmonary flow using the Fick principle; Dr. Dexter has placed proper emphasis on this problem. This is something that must be remembered when we calculate pulmonary resistance with high pulmonary flows, and we must avoid drawing too definite conclusions regarding the change in resistance following the cure of large left-to-right shunts.

Any physician, intimately concerned with the diagnostic problems presented by patients who have congenital heart disease, probably will admit two things: (1) his clinical diagnostic ability has been increased many fold in the past ten years as the result of correlation of clinical findings and data derived from cardiac catheterization, and (2) in an occasional baffling case, the results of cardiac catheterization may be diagnostically inconclusive or even misleading.

One principle needs constant repetition and reemphasis. In the diagnostic approach all the facts in the history and examination should be carefully sifted and weighed; any single laboratory finding that superficially appears to be definitely diagnostic should be studied with care if it does not appear to fit with the other features of the case. As an example, the finding of arterialization of blood in the left atrium might be due to many causes, including: (1) sampling error, including difficulties related to differences in the saturation of the three main veins emptying into the right atrium, namely, the superior and inferior vena cava and the coronary sinus; (2) anomalous pulmonary venous connections; (3) ventricular septal defect, with the right-sided opening above or through the tricuspid valve, this shold be suspected after the occurrence of subacute bacterial endocarditis in patients who have ventricular septal defect; (4) rupture of an aneurysm of the sinus of Valsalva into the right atrium, and (5) persistent atrioventricular canal with a "low" atrial septal defect as well as the atrial septal defect itself.

Two procedures that have been introduced into the technique of cardiac catheterization and brought to a state approaching technical perfection by Dr. Wood and his associates, have added a great deal to the diagnostic accuracy of cardiac catheterization.

The first is the use of the oximetric curvette to give nearly instantaneous readings of oxygen saturation of the blood at the tip of the catheter. This allows many determinations to be made; in addition, continuous sampling during withdrawal of the catheter from one part to another permits small differences in the oxygen saturation between such parts to be validated.

The second procedure is injection of dye into various parts of the central cardiovascular structures. This has had the rewarding results of fairly reliable localization and quantitation of venous arterial shunts.

Certain concepts presently held concerning four of the most common congenital malformations may be of some interest:

A. *Atrial septal defect.*
   1. Preferential drainage of the right lung to the right atrium exists in the majority of cases.
   2. Slight modifications of bilateral shunting are demonstrable by postural and respiratory maneuvers.
   3. Preferential drainage of the inferior vena cava toward the left atrium often is demonstrable.
   4. Functional openings of the foramen ovale with right-to-left shunting may occur after pulmonary embolism or pulmonary disease.
   5. Easy catheterization of the left ventricle through an atrial septal defect may be suggestive of the partial form of a common atrioventricular canal (auriculoventricular commune).
   6. In anomalous pulmonary venous connections, one should also suspect the presence of an atrial septal defect.

B. *Ventricular septal defect.*
   1. Many "transitional" conditions exist between uncomplicated ventricular septal defect and cyanotic Eisenmenger's complex.
   2. Severe pulmonary hypertension may coexist with a left-to-right shunt (pulmonary blood flow greater than the systemic) without hypoxemia.
   3. Cardiac failure in early infancy is not infrequent and may be associated with clinical evidence of left ventricular enlargement.
   4. Diastolic shunting of blood may be an important avenue of investigation.

C. *Patent ductus arteriosus.*
   1. The time of appearance of the continuous murmur is variable.
   2. Evidence of associated defects, particularly coarctation of the aorta and ventricular septal defect, is to be searched for.
   3. A patent ductus arteriosus is to be considered as the possible cause of cardiac failure appearing in early infancy.
   4. The disease in adult patients who do not have continuous murmurs and "reversed" shunts may be of two types: (a). An unchanged pattern since infancy, with no evidence of previous left-to-right shunt and no cardiac enlargement. (b). Acquired pulmonary hypertension and true reversal of shunt, which often may be exaggerated by breathing mixtures that are low in oxygen.

D. *Pulmonary stenosis.*
   1. Many difficulties in the evaluation of the subpulmonic tract remain, even though the problem has been approached through cardiac catheterization, blind surgical exploration and anatomic dissection.
   2. Extremely large hearts, as manifested by their roentgenologic silhouettes, may be present in infants who have isolated pulmonary stenosis.
   3. Surgical exploration sometimes deserves precedence over cardiac catheterization.
   4. Left-to-right shunts (pulmonary blood flow greater than the systemic) at either atrial or ventricular levels may coexist with severe pulmonary stenosis.
   5. Mild pulmonary stenosis is a definite entity, although its anatomic basis is obscure.

Time does not allow discussion of the difficult diagnostic problems often presented by the newborn or young cyanotic infant or the difficulties in the interpretation of murmurs, electrocardiographic records or roentgenologic findings. This often is best done by presentation of cases. This symposium has, I think, been properly oriented toward the discussion of broad concepts and of accurate measurment of hemodynamic variables.

In closing, it is proper to pay tribute to Dr. Cournand, who demonstrated the relative safety and value of cardiac catheterization in man, but to emphasize that this procedure does present some risk to the patient, the mortality rate probably approximating one death in 500.

Dr. Paul Adams, Minneapolis, Minn.: At the University of Minnesota, we have been particularly interested in what we consider the most challenging and difficult problem in the differential diagnosis of congenital heart disease, that is, infants under two years of age.

Challenging, because next to prematurity, it has been the largest single cause of infant mortality in Minnesota. Review of our autopsy material reveals that a certain number of these patients had defects which could have been corrected or improved by present surgical techniques. An ever-increasing variety of malformations may soon be similarly considered.

We consider it difficult because, in our experience, symptoms and findings in the infant differ markedly from the classical descriptions when malformation is severe. We are gradually becoming aware of findings, which are fairly typical of each individual malformation in the infant. We have often been asked, and indeed occasionally ask ourselves, just how much is accomplished by these special procedures in the infant, compared to the added risks involved? With that question in mind, our recent experience with heart catheterization in infants will be briefly outlined.

Right heart catheterization has been performed in fifty-three infants under two years of age—about 40 per cent of the total number of pediatric catheterizations during 1952-1953. Angiocardiography and retrograde aortography were done on seventy-four infants during the same period. These special procedures were undertaken only when the infants were considered to be severely handicapped, when the risk of death during infancy appeared to be greater than the risk of special procedures, and when the specific type of malformation could not be diagnosed by routine methods. The smallest patient weighed only 3 kilograms at four months of age. Of the total of 127 special procedures (heart catheterization, angiocardiography and retrograde aortography, one death occurred during heart catheterization. This death was probably related to the medications used rather than the procedure, *per se*.

The final diagnoses of the fifty-three patients who had heart catheterization studies are listed as follows:†

1. Patent ductus arteriosus	6
2. Coarctation of the aorta	3
3. Interatrial septal defect	3
4. Interatrial plus interventricular or A-V canal	4
5. Anomalous pulmonary venous drainage into the right atrium	5
6. Interventricular septal defect or Eisenmenger's	13
7. Tetralogy of Fallot	7
8. Transposition of the great vessels	5
9. No left-to-right shunt	
(a) aortic stenosis	4
(b) endocardial fibrosis	3

Patent ductus arteriosus is the malformation in which the greatest salvage has been obtained. All patients had been severely ill with respiratory infection, and/or growth retardation, and their survival had been considered doubtful. None of these infants had the typical continuous murmur. The location and character of the systolic murmur only occasionally was suggestive of the patent ductus ateriosus. Surgical closure of a very large ductus was successfully accomplished in every case with marked improvement. One diagnostic error occurred in which the oxygen saturations of the pulmonary artery were increased over the remaining venous samples. However, at surgery and at post mortem a high interventricular defect alone was found. This occurred before we were using retrograde aortography. Since that time we have used that method successfully in three additional cases.

Three out of a total of ten infants, who were operated on for coarctation of the aorta, were considered to need heart catheterization studies prior to surgery because of the suspicion of serious intracardiac defects. Although surgery was not denied any of these patients, a more guarded prognosis could be given.

The "flush" method for determination of blood pressure has been most helpful in infants. Occasionally, when the infant is crying or struggling during the examination, an unusually high blood pressure has been found in the arms in normal infants but normal pressures in the leg when done subsequently. To avoid this possibility of error in young infants we have simply joined two infants' cuffs together with a Y tube connector and taken pressures of the arm and leg simultaneously by the "flush" method. In the normal infant without coarctation, the leg flushes slightly before or simultaneously with the arm. In coarctation the flushing of the leg is delayed.

Transposition of the great vessels and tetralogy of Fallot can best be diagnosed by angiocradiography.

Although seven patients had no demonstrable left to right shunts, we feel that they were valuable in localizing the lesion to the left side of the heart. Two patients thought to have endocardial fibrosis clinically before catheterization, were shown to have patent ductus arteriosus as a result of catheterization.

The results of our diagnostic efforts have in many instances been encouraging, especially in those infants where excellent surgical correction has been accomplished. At times we have been disappointed, but overall, we feel that these sick infants deserve every effort of diagnosis that we can make.

We have felt that valvular pulmonary stenosis could be easily distinguished from infundibular stenosis by the characteristic sharp change in pressure at the valve in the valvular type, and the slower transitional change in the infundibular type. On two occasions, however, this sharp transition occurred and at thoracotomy they were found to have an infuidibular type. Both of these patients showed a small left to right shunt in the right ventricle in addition.

I should like to ask (a) whether this experience has occurred elsewhere? (b) if so, what explanation can be offered as to why it occurs, and (c) is there a way that this error may be avoided in the future?

Dr. Dexter mentioned the use of certain drugs and exercise as a differential aid in cases of suspected pulmonary hypertention, as opposed to the aorta arising from the right ventricle.

We have had one death in a patient with pulmonary hypertension following fluorescein circulation time, and recently the *New England Journal of Medicine* has reported such a case with mortality following a decholin circulation time. I would like to ask Dr. Dexter if he feels that the use of drugs or exercise in such a situation might be considered to add more risk to the procedure of heart catheterization than they care to undertake.

Dr. Dexter stated, if I understood him correctly, that in the absence of a significant shunt as shown by oxygen saturations during a satisfactory heart catheterization, any defect that existed could be safely considered as clinically insignificant.

An exception to this, I believe, might occur in a high interventricular septal defect with pulmonary hypertension, at a certain point where the right ventricular hypertension was balanced with the left so that no left to right or right to left shunt occurred, and yet the defect obviously would be clinically significant.

---

†It should be stressed, as Dr. Dexter stated, that heart catheterization was only one factor in the diagnosis. The patient's history, physical examination, x-ray, angiocardiogram and retrogradeaortogram were occasionally necessary. In some instances, the correct diagnosis was learned only during postmortem examination.

DIAGNOSTIC APPLICATIONS OF INDICATOR DILUTION CURVES IN HEART DISEASE

H. J. C. SWAN, M.B., Ph.D., M.R.C.P. (Lond.)
Rochester, Minnesota

AN INDICATOR dilution curve shows the changing concentration of an indicator at a specific point in the vascular system at various times following its injection at some different point in the vascular system. Usually dilution curves of the indicator are obtained from the arterial system following rapid injection of the indicator into the venous system proximal to the pulmonary capillaries. An indicator substance should possess the following qualities: (1) The substance must be nontoxic and sterilizable in regard to pathogenic organisms. (2) The concentration of indicator should remain relatively constant for at least a short time and preferably should allow for storage over several days. Otherwise a supply of fresh indicator must be readily available. (3) Injection of the substance must be possible in a brief time and this injection must not cause cardiovascular responses. Thus the volume in which the indicator is contained must be small. (4) The indicator must not pass out of the vascular system in appreciable amounts for several minutes. (5) It must be possible to measure the concentration of indicator in blood or plasma with considerable precision.

The indicator in most common use is Evans blue dye (T-1824),[2,4,8] but saline solution was used by Stewart, and brilliant vital red and other dye substances by Hamilton and associates,[3] in their fundamental studies on the problem of dilution of an indicator by the circulation. Hamilton and associates[3,4] used a discontinuous method of sampling in which multiple small samples of blood were collected, the concentration of T-1824 in plasma was determined photometrically, and a concentration-time curve was constructed. From such curves it is possible to measure circulation times and to estimate cardiac output and central blood volume. But when the information to be derived from a dilution curve depends to a major extent on the contour of that curve then use of a continuous recording instrument would appear to be essential. The oximeter[13] and densitometer[6] are instruments which permit the continuous recording of the concentration of T-1824 in whole blood. However, fluctuations in the oxygen saturation of arterial blood which frequently occur in patients with cyanotic congenital heart disease will distort dilution curves of T-1824 recorded by these instruments. This serious disadvantage which is inherent in the oximetric technics renders certain radioactive isotopes attractive as potential indicators when problems pertaining to dose and recording devices are satisfactorily solved.

The observations to be discussed in this communication are based entirely on dilution curves of T-1824 recorded by means of the oximeter.

The pattern of dilution in a normal subject following injection of T-1824 into a peripheral vein is shown in Figure 1. The oximeter responds to decreasing transmission of light and hence to increasing concentration of dye by a downward deflection of the recording beam. A short interval, the appearance time, elapses between the injection of the dye and its first arrival at the recording instrument. Then there is a rapid increase in concentration to a peak, followed by a less rapid decline in concentration which is incomplete and merges into a second peak of concentration which is caused by return to the sampling site of dye which has passed the systemic capillaries.

After injection into a peripheral vein the following average normal values in seconds have been obtained: appearance time 14 (10 to 20); maximal concentration time 25 (16 to 35); buildup time 10 (7 to 15); disappearance time 16 (9 to 26) and recirculation time 21 (16 to 28).*

The most important physiologic factors modifying the dilution pattern are: the rate of flow through the system, the effective mixing volume of blood in the central vascular pool, the variation in volume and rates of blood flow in the blood vessels in the lungs, and the characteristics of flow in the aorta and blood vessels leading to the sampling site. As a rough generalization, an in-

Presented in the Symposium on Recent Advances in Cardiovascular Physiology and Surgery, University of Minnesota, Minneapolis, Minnesota, September 15, 1953.

Dr. Swan is Research Associate in the Section of Physiology, The Mayo Clinic, Rochester, Minnesota.

*Approximated values from Nicholson, Burchell and Wood.

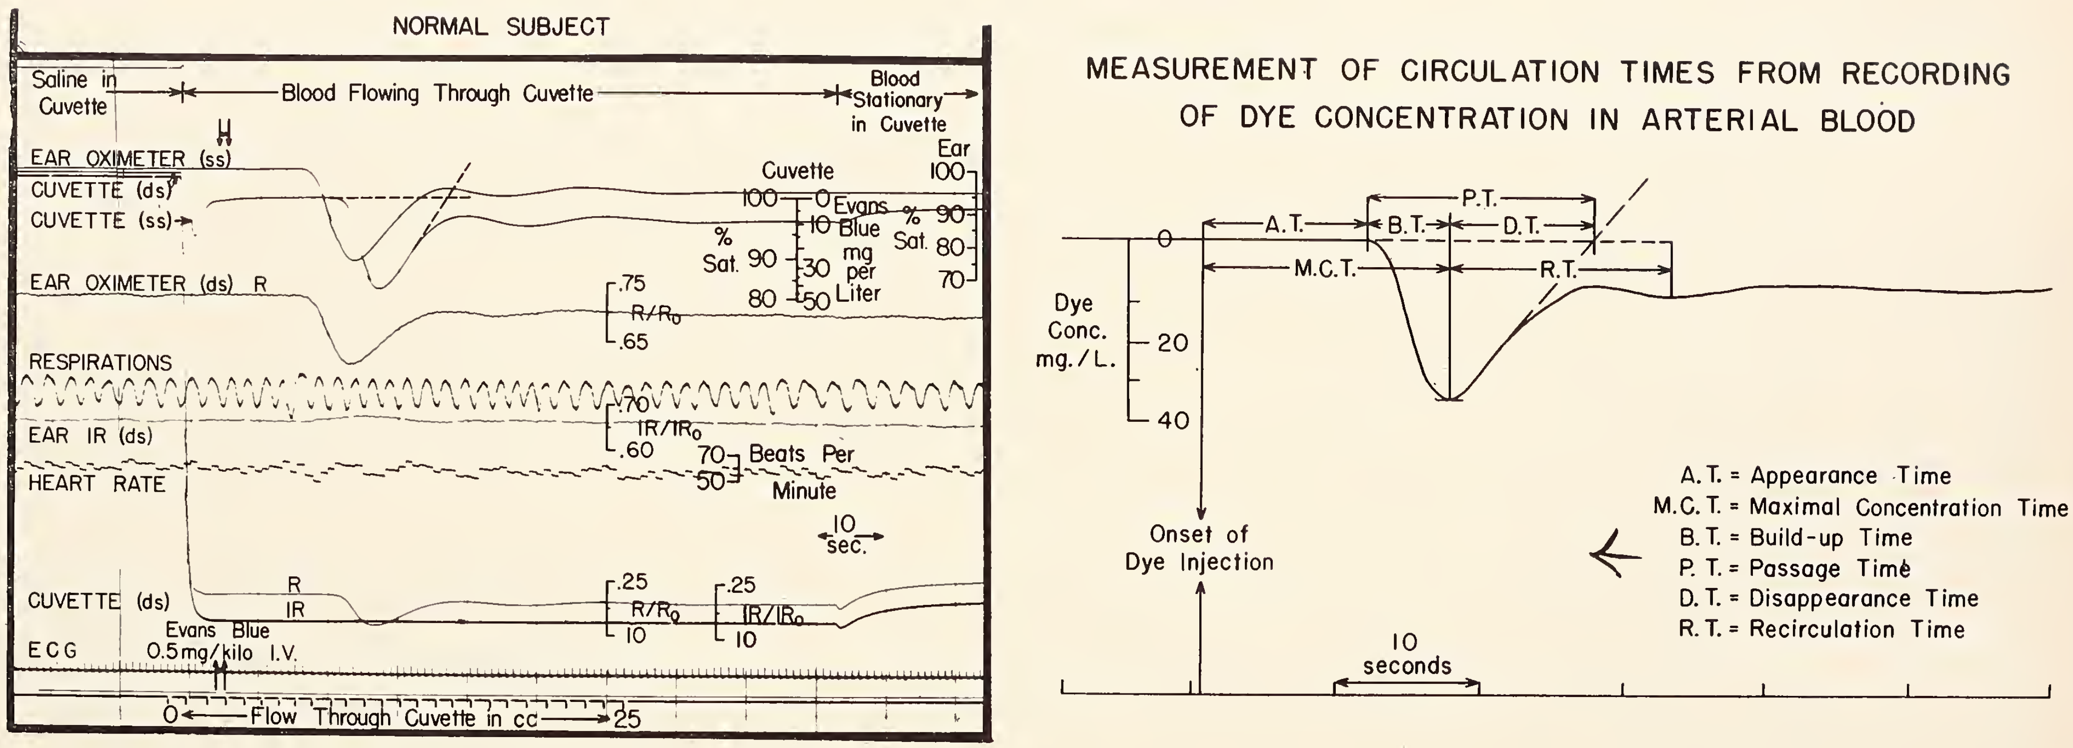

Fig. 1. Arterial dilution curves of Evans blue dye (T-1824) in a normal subject.

Left panel. A section of the photographic record, which is untouched apart from addition of captions. Curves were obtained from an oximeter on a heat-flushed ear, and from a cuvette oximeter through which blood from the radial artery was flowing. This panel shows recordings of the respiration rate, the heart rate, electrocardiogram, and rate of blood flow from the radial artery through the cuvette oximeter; also the change in transmission of red (R) and infrared (IR) light recorded by the oximeter (ds).

Right panel. The time components of the dilution curve are indicated.

crease in the volume of blood between the site of injection and the site of sampling causes a reduction in the concentration of dye, whereas a decrease in the rate of flow through the system results in prolongation of the time components. Therefore, in acquired heart disease, the changes in the dilution pattern found are those associated with reduced cardiac output and perhaps an increased volume of blood in the heart and great vessels.

In those forms of congenital heart disease characterized by an alteration in the circulatory pathway, the contour of the dilution curve may permit interpretations which have frequently been found to be of diagnostic value.

Conditions characterized by right-to-left or left-to-right shunts usually give rise to typical dilution patterns.[7] A dilution curve, following injection of dye into a peripheral vein of a patient with tetralogy of Fallot, is shown (Fig. 2, *left panel*). A shortened appearance time and an abnormal (first) hump on the buildup slope of the main curve are apparent. This pattern of dilution may be explained by the passage of a portion of the dye across the ventricular septal defect directly into the systemic circulation. The appearance time is reduced because this shunted dye reaches the recording instrument before the dye which traverses the longer, normal circulatory path through the lungs. As each portion of dye is subjected to dilution in its passage through the heart and the blood vessels, its arrival in the peripheral circulation takes the form of two curves which partially overlap. In many patients with right-to-left shunts the cardiac output may be normal, but because some dye passes through the defect, the maximal concentration is reduced from that in the blood of the normal subjects. Early in our experiences with dilution curves obtained from patients with intracardiac shunts, it became apparent that the contour of the dye curve is determined largely by the volume of shunt passing through the defect. Thus, in patients with severe cyanosis, the initial (abnormal) deflection was found to be as large or larger than the normal component of the curve, while a very small initial break was found in patients with very small right-to-left shunts producing only a minimal depression of arterial oxygen saturation. If certain assumptions are made, the magnitude of the shunt can be calculated from such curves,[12] and satisfactory agreement has been shown between shunt values calculated from the dilution curve and data obtained from cardiac catheterization. There was a standard deviation between the methods of ± 7 per cent of systemic blood flow in shunts ranging from 51 to 8 per cent of the systemic flow.

In left-to-right shunts also the dilution of indicator is altered in a specific manner[7] (Fig. 2, *right panel*). The appearance time and the buildup time are normal. However, the magnitude of the deflection is reduced, and the slope of declining concentration of indicator is much prolonged. Also, no peak due to systemic recirculation can be identified. This curve, which is typical of left-to-right shunt of considerable magnitude, is explained on the basis of recirculation of dye in the heart and vessels of the lungs with a slow clearance of a constant proportion of the recirculating dye into the systemic arterial system. This slow elimination of dye results in the prolonged disappearance time which is the most notable feature of the curves. Since, in normal subjects, sharpness of individual dilution curves varies considerably, yet the curve remains consistent with regard to internal time relations, the ratio of disappearance time to buildup time of abnormal curves provides a sensitive index of disproportionate prolongation of the disappearance time. Broadbent recorded dilution curves following peripheral injections of dye into sixteen patients with left-to-right shunts and compared the ratio of disappearance time (DT) to buildup time (BT) with the magnitude of shunt calculated on the basis of values of oxygen saturation obtained at cardiac catheterization. An approximate relation based on these data indicated that the arteriovenous shunt expressed as per cent of the pulmonary artery flow equals $10 + 10$ (DT/BT).

These dilution patterns then are typical of right-to-left and left-to-right shunts, respectively. They are dependent not only on the existence of a defect but more fundamentally on direction and volume of blood flow across it. Abnormal dilution patterns will not be seen when the pressures on either side of a defect equal one another at all times, because in this instance no shunting of blood will occur.

Since the altered dilution pattern in right-to-left and left-to-right shunts depends on the presence of an abnormal circulatory path, it appeared

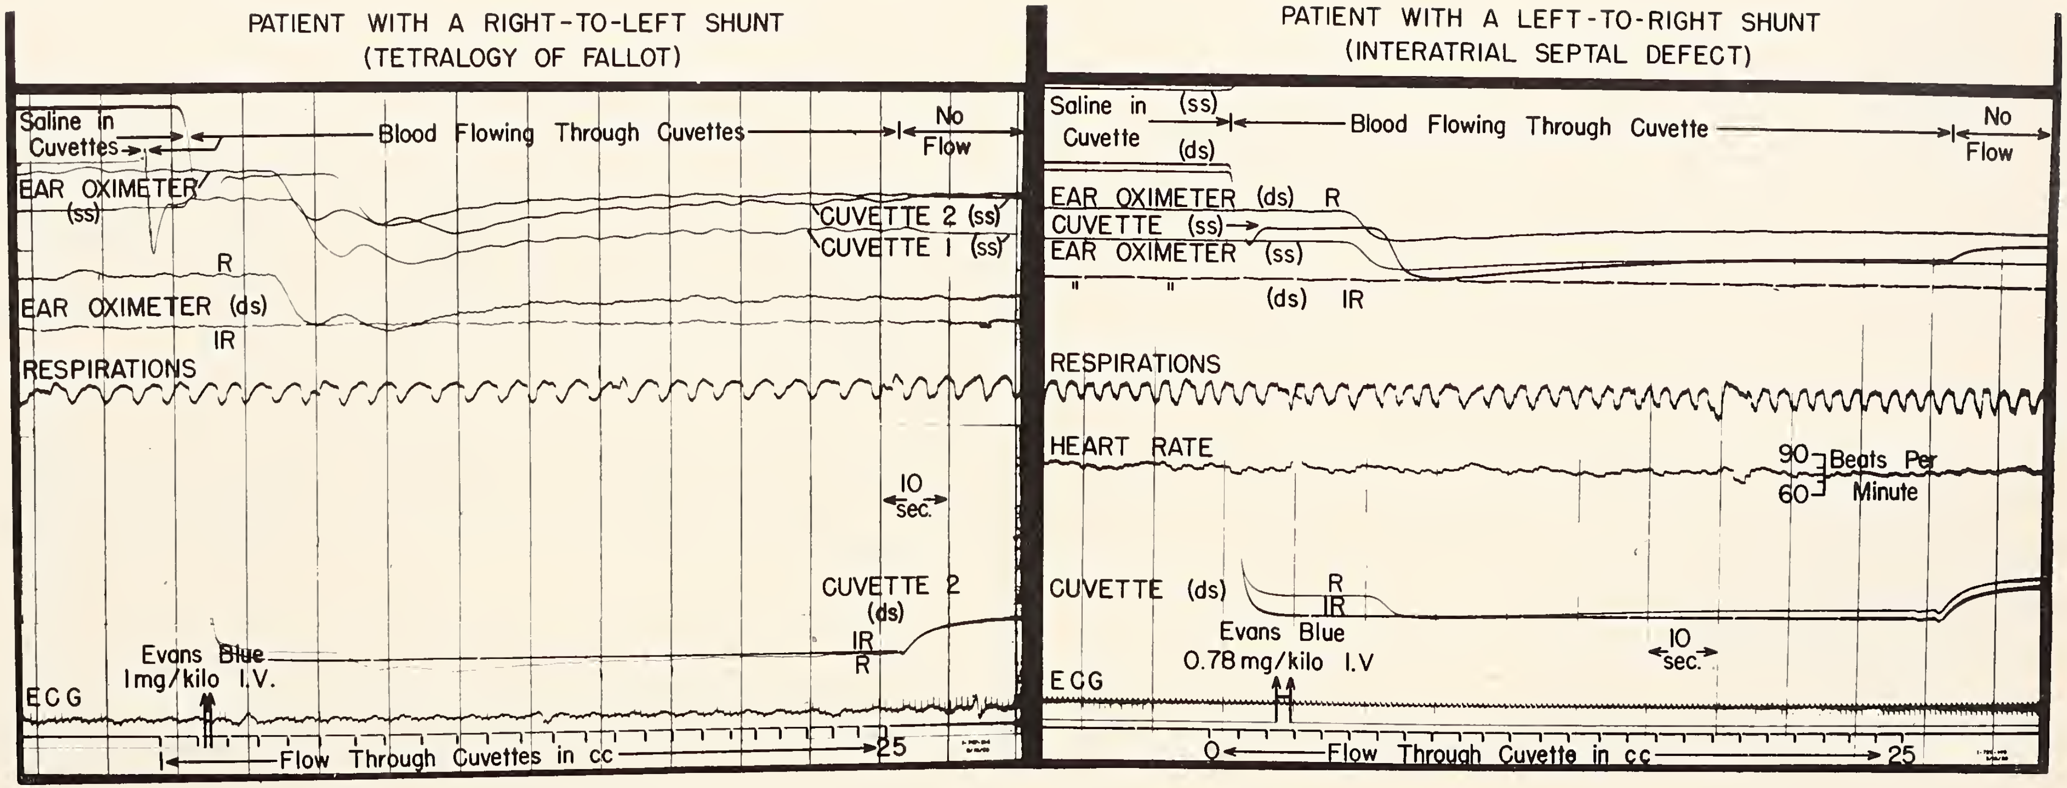

Fig. 2. Recording of dye dilution curves obtained after peripheral injection of T-1824 into a patient with tetralogy of Fallot *(left panel)* and in a patient with an atrial septal defect *(right panel).*

Left panel. The dilution curves were recorded by an oximeter on the heat-flushed ear (ear oximeter ss) and by two cuvette oximeters in tandem (cuvette 1 ss and cuvette 2 ss) through which blood from the radial artery was flowing. The short appearance time (8.5 seconds for the ear oximeter) and the double-hump pattern seen on all curves should be noted. The normal peak due to recirculated indicator is absent. The changes in both cuvette curves were delayed due to the time necessary for dye to pass from the radial artery to the photosensitive portion of the cuvette oximeters. Small fluctuations may be noted in the recording line due to variations in oxygen saturation coincident with respiration. This form of dilution curve is typical of right-to-left shunt.

Right panel. The dilution curves from a patient with an atrial septal defect recorded by means of an earpiece oximeter (ear oximeter ss) and by a cuvette oximeter (cuvette ss) through which blood from the radial artery was flowing. The normal appearance time (11 seconds for the earpiece), the reduced magnitude of the initial deflection and the marked prolongation of the disappearance slope of the dilution curve should be noted. This type of curve is typical of left-to-right shunts.

possible to obtain additional information from dilution curves recorded after injection of dye at several different sites in the heart and great vessels of the same individual.[11] In normal subjects, and in patients without intracardiac or extracardiac shunts, the dilution pattern following injection of dye into the pulmonary trunk differed somewhat from that following injection at a more peripheral site. After peripheral injection the concentration components were reduced, and the time components were prolonged. This phenomenon was explained on the basis of greater longitudinal mixing and dilution after injection into the more peripheral vessels.[5] The curves were, however, similar to one another in general contour. In cases with right-to-left shunts it became possible to localize the site of a defect with relative certainty (Fig. 3). If an injection of dye is made distal to the site of a defect then a relatively normal pattern of dilution is obtained, because dye traverses a fundamentally normal circulatory pathway. But if the injection is made at or proximal to the defect then some of the dye will be shunted through the defect while the remainder traverses the pulmonary vascular bed, thus producing the abnormal "double-hump" pattern. By this technique right-to-left shunts occurring through a patent ductus arteriosus, ventricular and atrial septal defects have been localized and, in many instances, identification would not have been made otherwise. It has been possible to recognize small right-to-left shunts, particularly those occurring at the atrial level, which caused an insignificant desaturation of the systemic arterial blood.

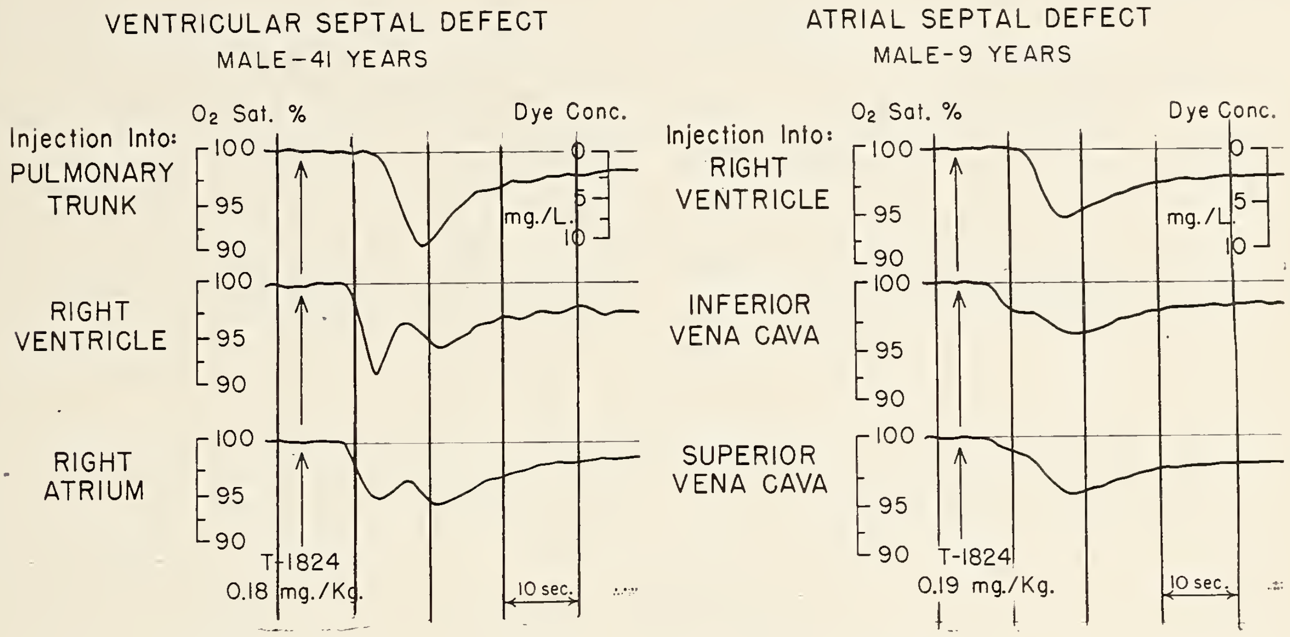

Fig. 3. Localization of the site of a right-to-left shunt in a patient with a ventricular septal defect, and in one with an atrial septal defect. In each case the curves have been superimposed in regard to the time of dye injection. The oxygen saturation scales serve to indicate the relative sensitivity of the oximeters.

Left panel. Dilution curves from a patient with Eisenmenger's complex recorded after injection of T-1824 into the pulmonary trunk, right ventricle and right atrium. Fluctuations in oxygen saturation may be noted in all curves. The appearance time after injection of dye into the pulmonary trunk is normal for this site (9.0 seconds) and the remainder of the curve is not grossly distorted. The curves after injection of dye into the right ventricle or the right atrium differ from the curve after injection in the pulmonary trunk in that the appearance time is shorter (5.5 seconds) and there is a well-defined double-hump pattern. This series of curves localizes the site of the right-to-left shunt and, hence, of the intracardiac defect to the ventricle.

Right panel. Curves obtained after injection of dye into the right ventricle, inferior vena cava and superior vena cava in a patient with atrial septal defect. The curve after injection of dye into the right ventricle has a normal appearance time (8 seconds) and build-up slope, but the disappearance time is prolonged. This prolongation of disappearance time indicates the presence of a left-to-right shunt. In the curves obtained after injection of dye into both inferior and superior venae cavae, the appearance time is reduced (4 seconds) and a double-hump pattern is apparent. In this instance, the defect can be localized to the atrial septum. The right-to-left shunt from the inferior vena cava is indicated by the curve being of greater relative magnitude than that from the superior vena cava.

In cases with left-to-right shunt recirculation of dye occurs after the dye has passed the pulmonary capillaries, hence specific differences between injections into the pulmonary trunk and more peripheral sites would not be expected. In a relatively limited experience with the central injection technic in patent ductus arteriosus and ventricular septal defect no remarkable distinguishing features have been apparent. However, in both atrial septal defect and anomalous pulmonary venous connection, striking differences in the dilution pattern have been obtained after injections into right and left pulmonary arteries, and after injections into either right or left pulmonary artery and pulmonary trunk.[10] Findings typical of atrial septal defect are shown in Figure 4. The curve from injection into the right pulmonary artery differs from that following injection into the left pulmonary artery in that the magnitude of the deflection is smaller and there is a well-marked second hump about six seconds after the first. These differences in deflections are due to a smaller amount of dye passing from the right lung into the left ventricle and systemic circulation. The remainder of the dye is shunted into the right atrium and passes again through the pulmonary circulation. The second peak is produced when a portion of this shunted dye passes out (mostly by way of the left pulmonary artery) to the systemic arterial circulation. The interval between the two peaks of concentration represents the average time which the dye takes to circulate once through the lungs. The finding of this difference between dilution curves from the right and left pulmonary artery demonstrates that in many cases of atrial septal defect a greater proportion of blood draining from the right lung is shunted in a left-to-right direction than is that from the left. This phenomenon probably is due to the proximity of the openings of the right pulmonary veins to the defect in the atrial septum.

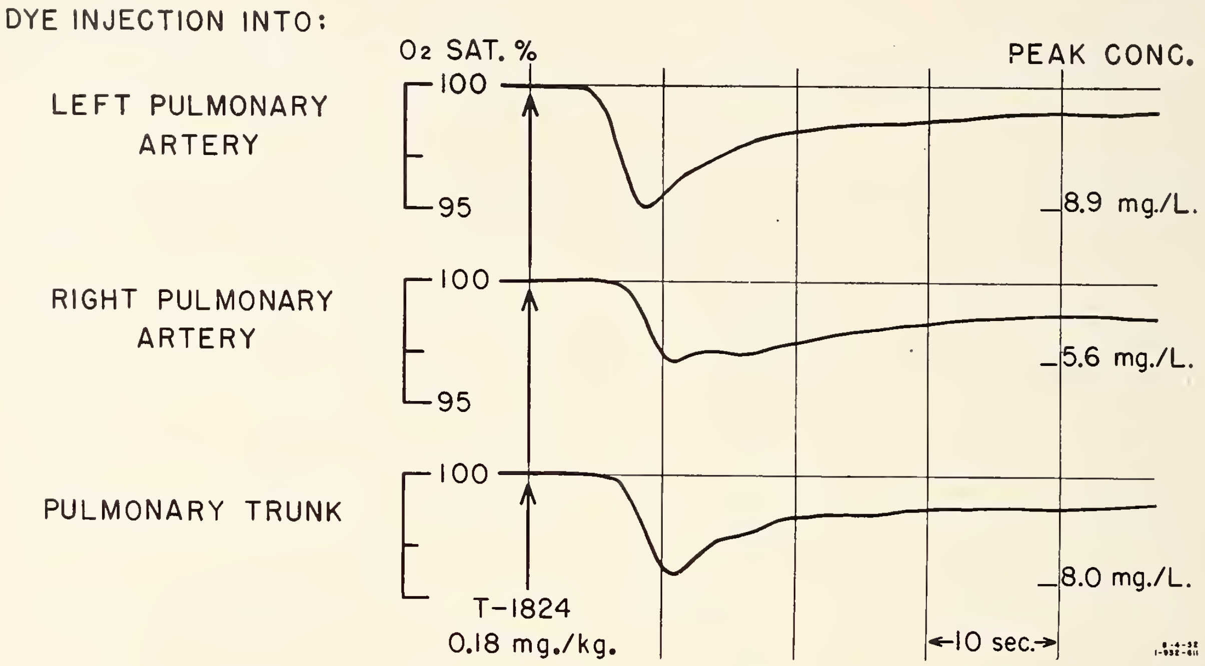

Fig. 4. Dye dilution curves obtained after injection of T-1824 into the left pulmonary artery, right pulmonary artery and pulmonary trunk of a sixteen-year-old girl with atrial septal defect. Injection of dye into the left pulmonary artery resulted in a dilution curve with a normal appearance time and build-up slope, but with a prolonged disappearance time, indicative of a moderate degree of pulmonary recirculation. After injection of dye into the right pulmonary artery, however, the magnitude of the initial deflection is reduced, and there is a well-developed second hump on the disappearance slope. The curve following injection into the pulmonary trunk is a composite of both right and left pulmonary arteries (for discussion see text).

In partial anomalous venous connection, the veins from one lung communicate directly with either the right atrium or one of its tributaries. This situation is associated with an anomalous drainage of the blood from that lung; hence, injections of dye into the right and left pulmonary arteries will serve to identify this condition in many instances. In the case of the anomalously draining right lung (Fig. 5) the appearance time is considerably prolonged, and the magnitude of the deflection is reduced in comparison with the curves from the normally draining left lung. If equal volumes and equal rates of blood flow through each lung are assumed, then the prolonged appearance time following injection into the right pulmonary artery is due to the greater distance between the sites of injection and of sampling. This distance includes the pathway through the pulmonary vascular bed and right side of the heart which the dye has to traverse to reach the normally draining left lung which is the only route through which dye passes to the systemic circulation. Division of this dye in the pulmonary trunk into portions traversing the right and left lung reduces the total amount of dye passing to the systemic circulation and hence diminishes the magnitude of the resulting deflection. Recirculation of the remaining dye through the anomalous pathway causes a prolonged clearance of dye from the central circulation and, therefore, an increased disappearance time. When an anomalous pulmonary venous connection into the right atrium coexists with a defect of the atrial septum, it may not be possible to demonstrate the presence of an anomalous connection with certainty.*

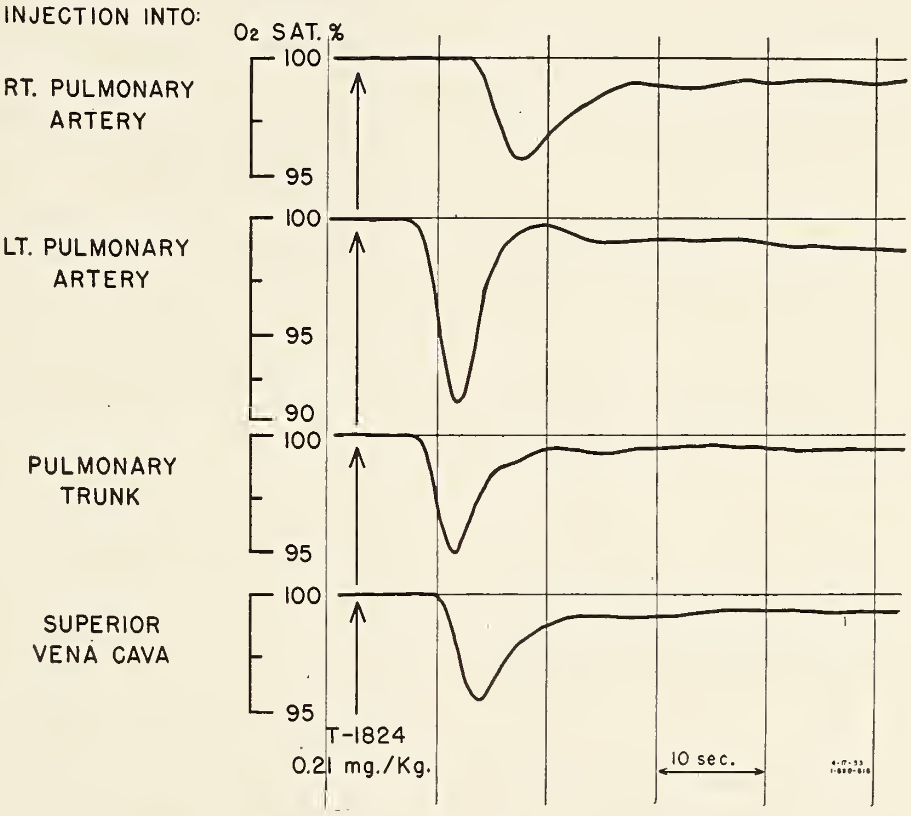

Fig. 5. Arterial dilution curves recorded following injection of T-1824 into right, left and main pulmonary arteries and superior vena cava of a forty-three-year-old woman with anomalous pulmonary venous connection and agenesis of the upper lobe of the right lung. The curve obtained after injection into the left pulmonary artery is normal (appearance time, 5 seconds). In contrast, curve obtained on injection of dye into the right pulmonary artery shows the appearance time is much prolonged (10.3 seconds), the magnitude of the deflection is reduced, and the disappearance slope is prolonged (for discussion see text).

Summary

Analysis of indicator-dilution curves based on differences in contour and time relationships offers a new tool in the study of heart disease. In particular the method permits a more detailed study of the dynamics in congenital heart disease and hence permits better appraisal of the anatomic defect present. In this presentation certain of the concepts basic to the technic have been outlined. In the individual case the physician at catheterization makes use of the methods as he proceeds with the study since careful selection of sites of injection on the basis of data being obtained during the procedure, will allow a more precise diagnosis to be made. In the cardiac catheterization laboratory of the Mayo Clinic this technic is an established integral part of the routine investigation of the majority of cardiac patients studied. In these days of the increasing possibility of successful surgical therapy for congenital heart disease the added accuracy of diagnosis provided by the technic has proved to be of practical value.

STROKE VOLUME CHANGES

(Continued from Page 115)

that of Dr. Remington in the assumption of a linear volume-pressure relationship, the slope of which is measured in each individual, while Dr. Remington accepts this individual variation by utilizing an average curve.

Since many assumptions and approximations are of necessity made in the derivation of the equations used, care must be taken to carefully control studies made with this technique by simultaneous determinations using independent methods. This is particularly true when used in conditions other than those already tested.

MINNESOTA MATERNAL MORTALITY STUDY

The Maternal Mortality Committee of the Committee on Maternal Health of the Minnesota State Medical Association

THIS REPORT is the third concerned with the statewide maternal mortality study being carried out in Minnesota. The present report deals principally with the results of the current study, which includes the period April 1, 1951, through March 31, 1952. Certain comparisons are made between these results and those of the preceding year and with the results of a similar study carried out in Minnesota from July 1, 1941 to June 30, 1942. (The three surveys will hereafter be referred to as the "1951 survey," the "1950 survey," and the "1941 survey," respectively.)

The study of maternal deaths is sponsored by the Minnesota State Medical Association and the Minnesota Department of Health with the latter organization providing the necessary funds. Each death is thoroughly studied in a personal visit by a trained obstetrician, and the data so obtained is then considered in a completely impartial manner by the Maternal Mortality Committee of the Maternal Health Committee of the State Medical Association. The exact method by which the study is carried out has been detailed in a previous report.[1]

It is gratifying to note that a further reduction in the maternal mortality rate occurred during the period covered by the present report (Table I). For the purposes of this study, all deaths associated with pregnancy and those occurring during a period of three months postpartum are included, regardless of cause of death. In many instances it has been clear that the pregnancy or the postpartum state had no direct relationship to the cause of death, but these deaths are nevertheless included in this study for completeness. This group of cases constitutes the so-called non-obstetric deaths. The remaining deaths (excluding those due to chorionepithelioma which are also included in the present report) are those from which state and national maternal mortality rates are ordinarily calculated. Deaths due to chorionepithelioma are not included as maternal deaths in state and national rates, but are customarily included in reports on cancer. In Table I are shown the all-inclusive maternal death rates and the "maternal death" or corrected rates for each of the three years referred to. It can be seen that the reduction in the maternal death rate in Minnesota has been progressive and that the rate is consistently well below that of the United States generally.

**Unofficial.
†Including all maternal deaths from whatever cause.
‡Excluding deaths considered as non-obstetrical on the basis of the definitions set down by the United States Bureau of the Census. This is the ordinarily reported maternal mortality rate.

The comparison would be even more favorable to Minnesota were it not for the fact that in the three years of the study, thirty-nine cases have been added to the totals for this state by special efforts at case finding. These cases have included eight "obstetric deaths" and have been discovered principally by cross-matching birth and death certificates and by reports of various individuals interested in the study. In all thirty-nine instances, there was no mention of pregnancy or the postpartum state on the death certificate. Since the number of maternal deaths is customarily arrived at from information appearing on death certificates, none of the thirty-nine would have been included in the determination of maternal death rates had it not been for the special efforts undertaken to discover them. It is the opinion of the Committee that very few if any maternal deaths in Minnesota escape recognition under present circumstances.

Many factors are probably involved in the continuing reduction of maternal mortality. These include increased use of whole blood, the availability of various chemotherapeutic and antibiotic agents, and extensive use of hospitals for obstetrical deliveries. In the final analysis, the chief

credit is obviously due to the practitioners in Minnesota who are engaged in practicing obstetrics and who are ultimately responsible for careful obstetric work and for applying to actual practice the advances being made. The achievement of a mortality rate that was considered to be the irreducible minimum at the time of the original state survey in 1941 must mean that the great majority of Minnesota physicians are administering extremely efficient obstetric care. The material collected in the three years of the survey shows real evidence of improvement in this care.

Perhaps the most noteworthy evidence of improvement concerns preventability of death, as shown in Table II. In 1941 almost three-fourths of the deaths were considered preventable, while in 1950 and 1951 only about one-third and two-fifths, respectively, were preventable. In each year the physician involved was charged with the responsibility for the great majority of the preventable deaths.

That some improvement has taken place with regard to consultations is indicated in Table III. It will be noted that adequate consultation was obtained in less than 10 per cent of cases in 1941, but that this percentage was more than tripled in 1950 and again in 1951. There is room for further improvement here. Consultation was thought to be indicated in an additional 25 per cent of cases in 1951.

The data in Table IV indicate a continuing increase in the relative numbers of autopsies being done. Since trained personnel are frequently not available for the performance of an autopsy, the figure of 40 per cent for adequate postmortem studies in 1951 is considered good.

Another indication of improvement in obstetric care is the increase in the percentage of deaths associated with pregnancy that are due to non-obstetric causes, as shown in Table V. In the last two years of the survey almost one-third of all the deaths were due to non-obstetric causes as compared with less than one-fifth of the 1941 deaths.

While the evidence of improvement in care is most encouraging, much more improvement is still possible as indicated by the material obtained in the studies. It is not assumed that the material covered by the study is at all representative of the practice of obstetrics in the state as a whole. Since all the patients died, it is much more likely that the material so gathered contains a considerable concentration of evidence of bad obstetrics. At the same time it does indicate where improvements can be made.

Adequate care as defined by the Committee in its list of minimum requirements is being given to a pitifully small percentage of the patients who die (Table VI).[1] That these deficiencies are not mere technicalities is indicated by the frequency with which various deficiencies in care contributed to the patient's death. The encouraging evidences of improvement cannot be allowed to obscure the fact that approximately

40 per cent of the deaths occurring are still preventable. The number and variety of faults in management comprise a long list. In the majority of instances the disastrous outcome was not the result of lack of some specialized knowledge or ability on the part of the physician, nor to lack of facilities, but rather to failure to follow principles of care familiar to all physicians.

The following examples taken from the 1951 survey may serve to illustrate this point. One patient died of a ruptured uterus resulting from attempted podalic version and extraction following a prolonged obstructed labor at term. The obstruction was due to the presence of a large sarcomatous mass in the pelvis which was missed because a pelvic examination was not done. No fewer than seven patients were delivered by accouchement forcé, a procedure which is probably never indicated. Six of the seven died from hemorrhage as a direct result of the procedure. Three patients died as a result of complete lack of attention to fluid and electrolyte balance. Two of these were suffering from hyperemesis gravidarum while the third died on the eighth day after delivery by cesarean section. Despite the fact that the patient vomited frequently, had a negligible oral intake of food and fluid, and was subjected to gastric aspiration for more than three days, she was given no sodium, potassium or chloride until just before death and never more than 1,000 cc. of fluid parenterally daily.

Pelvic measurements are still obtained in only one-fourth of the cases (Table VII), and serology during the prenatal course in considerably less than one-half (Table VIII). Surely the value of these procedures does not need re-emphasizing, yet the frequency with which they are done in the cases being studied is increasing only very slowly.

As indicated in Table IX, the relative incidence of operative deliveries is not changing significantly although the absolute incidence is. Approximately 40 per cent of the operative deliveries studied in the last two years of the survey were considered to be not indicated. More importantly, in 1951, 45 per cent were considered contributory to death.

Results of 1951 Survey

Table X contains the details regarding cause of death as determined by the Committee in the cases studied in 1951. Much of the information is self-explanatory but a few points require elaboration. It will be seen that hemorrhage was

Totals		57	100.0

by far the leading cause of death. Almost one-half of the deaths due to hemorrhage were accounted for by the manual dilatations of the cervix previously referred to, none of which were indicated. Two of the remaining three patients who bled to death from lacerations of the birth canal had been given subcutaneous obstetrical pituitrin before delivery. One of the two cases of intrapartum hemorrhage involved a patient with a twin pregnancy who was sent back to bed after delivery of one twin. She died three and a half hours later of shock due to massive hemorrhage externally and into the uterus resulting from partial separation of the placenta. The second patient was delivered by an Indian midwife at home. The patient expired of hemorrhagic shock before the placenta was delivered.

The number of deaths due to infection continue to drop. As noted in Table X, pulmonary embolism accounted for two-thirds of the cases in this category.

TABLE XI. ANALYSIS OF MATERNAL DEATH CERTIFICATES IN MINNESOTA
1951 Study

	No.	Percent
Complete and correct	18	31.6
Complete but incorrect	8	14.0
Incomplete and incorrect	13	22.8
Incomplete, otherwise correct	18	31.6
Totals	57	100.0

TABLE XII. ANALYSIS OF BIRTH AND STILLBIRTH CERTIFICATES IN MINNESOTA
1951 Study

	No.	Percent	Percent of Those Required
Complete and correct	18	31.6	48.6
Complete but incorrect	14	24.6	37.8
Incomplete, otherwise correct	5	8.8	13.5
Not required	20	35.1	
Totals	57	100.1	99.9

A notable change between the 1950 and 1951 results concerns the toxemias. Toxemia was the leading cause of death in 1950, accounting for 19 per cent, whereas in 1951 the proportion had dropped to 7 per cent.

Failure to appreciate the intolerance of pregnant women to ordinary doses of anesthetic agents for spinal anesthesia accounted for two deaths. One patient received 150 mgm. of procaine and the other 18 mgm. of pontocaine. Both expired promptly of respiratory paralysis and shock.

Tables XI and XII are included to indicate the great need for improvement in the accuracy and completeness with which birth and death certificates are filled out. In eleven of the twenty-one incorrect death certificates, or 19.3 per cent of the total, the cause of death as determined by the Committee's investigation showed that the cause recorded on the death certificate by the physician concerned was incorrect.

Summary and Conclusions

1. A brief general summary of the results of the Minnesota Mortality Study for the period April 1, 1951, through March 31, 1952, has been presented. Certain comparisons are made between these results and those of the preceding year and with the results of a similar study carried out in Minnesota in 1941-1942.

2. There were fifty-seven deaths associated with pregnancy or the postpartum period in the 1951-1952 period among 80,099 live births for an over-all mortality rate of 0.712 per 1,000 live births. The rate when deaths due to non-obstetric complications are excluded was 0.45. This represents a further reduction as compared with the previous year's study and compares favorably with that of the whole United States. In 1951 the unofficial United States maternal mortality rate excluding non-obstetric complications was 0.71.

3. It is assumed that the remarkably low maternal mortality rate achieved means that efficient obstetric care is being administered by the vast majority of Minnesota physicians engaged in practicing obstetrics.

4. A significant reduction in the proportion of deaths that were considered preventable has taken place since 1941. Still more improvement is possible, since 42.1 per cent of the 1951 deaths were considered preventable.

5. There has been an increase in the percentage of deaths associated with pregnancy but due to non-obstetric causes—from 17 per cent in 1941 to 31.6 per cent in 1951. Thus, there is a significant decrease in deaths due to obstetric causes.

6. The percentage of adequate consultations obtained in 1951-1952 was more than three times that obtained in 1941.

7. Complete pelvic measurements were obtained in only 27.3 per cent of registered patients who died. This situation must be quickly improved. Serology was obtained in 43.2 per cent.

8. Of the delivered patients who died, 55.5 per cent were delivered by operative means. Of the operative deliveries, 40 per cent were considered not indicated and 45 per cent contributed to the patients' deaths.

9. As judged by the standard of minimum requirements for adequate obstetric care as adopted by the Maternal Mortality Committee, prenatal care was faulty in 86.3 per cent, care in labor and/or delivery was faulty in 74.5 per cent, and portpartum care was faulty in 57.6 per cent of the cases studied. The faulty care contributed to the patient's death in 22.7 per cent as regards prenatal care, 53.5 per cent as regards labor and delivery, and 45.5 per cent as regards postpartum care.

10. The primary cause of death is tabulated. Hemorrhage was the leading cause of death in 1951 with almost one-half of the deaths due to hemorrhage being accounted for by accouchment forcé. It is long past time for this procedure to be given up.

11. Adequate autopsies were performed in 40 per cent of the cases studied in 1951. This proportion is approximately five times the frequency with which autopsies were done in 1941.

12. Only 31.6 per cent of the death certificates and 48.6 per cent of the birth certificates reviewed were complete and correct. In 19.3 per cent, the cause of death as recorded on the death certificate was incorrect as determined by the Committee's investigation. The significance of this fact is clear. The validity of data obtained from unchecked death certificates is open at least to serious question.

13. The Committee would like to point again to the fact that in many of the hospitals in which these maternal mortalities are occurring, simple history taking, careful general and obstetric physical examination, and basic laboratory work are grossly deficient. That this is related to the end result for the patient is clear. The Committee would urge again that the medical and administrative staffs of such hospitals owe a duty to their patients to enforce the carrying out of these studies without exception. The minimum standards for adequate obstetric care as set down by the Committee are recommended.

14. The experience of the Maternal Mortality Committee would suggest that there are numerous sources of serious error in the usually reported maternal mortality rates. Case finding which depends on death certificate reports is incomplete and diagnoses from this source are grossly inaccurate. It is impossible to evaluate the accuracy of the division into so-called obstetric and non-obstetric deaths when only death certificate information is available.

15. The Committee is tempted to point out the justification for pride in the efficiency of obstetric care in Minnesota which these data indicate. It has overcome this temptation since there is clearly much to be improved and since pride and progress are uneasy bedfellows.

INTERVERTEBRAL DISC LESIONS IN THE TEENAGE GROUP

D. R. LANNIN, M.D.
Saint Paul, Minnesota

LOW BACK PAIN and mid-back pain with or without radiating pain into the leg is a fairly frequent complaint of both boys and girls in the teenage group. When a patient complains of lumbar or lumbosacral type pain one expects primarily to find evidence of some disease, such as tuberculosis, neoplasm or epiphysitis. When a patient in the teenage group, in addition to the back pain, complains of lower extremity radiation, one is highly suspicious of intervertebral disc type lesion. Radiating pain is not necessarily always present or associated with an intervertebral type lesion and in our series it is fairly common to have a well-established radiographic evidence of intervertebral disc pathology with no complaint of pain extending into either lower extremity. We have recently reviewed a rather large series of low back complaints in patients varying from sixteen to twenty years, nineteen of whom have come to laminectomy for an intervertebral disc lesion.

One of our greatest handicaps in the understanding and treatment of intervertebral disc lesion, both in teenagers and adults, is our limited knowledge of the cause of disc degeneration. There are many theories as to the cause of progressive degeneration in normal intervertebral discs, none of which have been definitely accepted by orthopedists. Because of the activity of both boys and girls in the teenage group it is quite common to attribute any progressive degenerative condition to repeated trauma or to one single episode of trauma. In spite of the fact that several of our intervertebral disc cases occurring in teenagers have been in association with athletic participation, we are rather impressed with the fact that the amount of precipitating trauma in this age group is rather slight.

All of us have seen a great many cases of low back pain in the teenage group which may have been associated with some minimal type lifting injury or athletic injury which would give rather marked difficulty for ten days or two weeks and then would spontaneously improve on bed rest and symptomatic treatment. A great many of these cases have a tendency to recur periodically but never reach the point of becoming bad enough to justify a spinogram or intensive work-up. I feel that in a great many of these cases there is progressive disc degeneration which perhaps represents the early phase in the large number of adult patients whose x-rays show long-standing degenerative disc changes. A very high percentage of these back complaints in teenagers respond very well to symptomatic treatment, including well-fitting wide lumbosacral belts. Certainly this age group, as well as adults should have a long period of conservative management before a laminectomy is considered. All of our patients who eventually require laminectomy were first given an extended period of initial bed rest, heat, sedation, and support.

I feel that in teenagers as well as adults with disc lesions and with unilateral sciatic radiation, only a small percentage actually obtain much improvement from traction. If traction is to be attempted it should only be for a trial period and if there is no definite improvement within forty-eight hours it should be discontinued. In the type of disc where a large free fragment is forced out of the intervertebral space and locked under the posterior ligament traction will definitely be of no value and will many times produce an increase of both back and leg pain. If, after the period of rest and conservative treatment there has been no improvement or insufficient improvement to allow return to activity further work-up is necessary. We feel that a spinogram is indicated in all these patients to more accurately localize the lesion and eliminate possibility of an unrecognized double disc.

I would like to briefly review nineteen cases of patients who eventually have come to laminectomy. Of these eight were girls and eleven were boys, the youngest of whom was sixteen and the eldest had presenting symptoms at the age of nineteen. Several writers have pointed out that in children and teenagers intervertebral disc lesions seem to be rather unusual in their lack of complaints of numbness, parasthesia, and muscle weakness. We have been unable to find any variation in presenting complaints or physical findings between the teenage group and the adult group with similar lesions. Some writers have stressed the high incidence of lumbosacral disc lesions in the younger group but here again in our series eight cases had an L-4-5 defect; ten cases had an L-5-S-1 defect and one patient, a girl of seventeen, had at the same time a large defect at L-5-S-1 on the right and at L-4-L-5 on the left. The history of an injury period here again is quite variable. Only three had the beginning of back and leg complaints after athletic participation. Eight had a completely insidious onset of pain associated with no injury of any type. Two, a pharmacy student and a high school student, first had difficulty when bending over to tie their shoes. Four had difficulty after some minor lifting injury. One had an initial complaint of back and leg pain after sneezing and the last, the girl with the double-disc lesion, first had difficulty after falling a distance of approximately eighteen inches from a kitchen stool. On examination the physical findings in these patients were not unusual. The subjective complaints of shooting and radiating pain which was made worse by coughing, sneezing and straining, were the most common. In five patients out of the nineteen who had no shooting type, radiating pain, a herniated disc was suspected because of the rather long period of severe incapacitating back pain. All patients but three showed a very definite change in reflexes and five out of the nineteen had a definite change in sensation. None showed appreciable atrophy or definite muscle weakness.

Several authors have mentioned the finding of unusually stringy, or gelatinous, material obtained from the intervertebral disc space. This may be true in very young children with whom we have had no experience but in our cases the pathological specimens have been very little different from those in the adults. In five or six patients with large bulging discs which have been opened, a single fragment has been freely removable. The remaining material in the disc space has had a rubbery consistency and we have had the feeling that this represents an unripe or incompletely degenerated form of disc disease. It is in these patients that the prognosis is rather reserved. We make every effort to thoroughly curette the disc space and remove all such material but there is always the possibility of further separation of further degenerating disc material which may later give rise to a secondary protrusion from the same disc space. In the one patient of the nineteen who has had recurrent difficulty, a second laminectomy established the presence of more degenerated material at the same level and on the same side in rather large amounts. Except in these cases where an unripe disc is established at laminectomy we feel the prognosis in teenage patients is rather good. All patients are given a follow-up consisting of developmental back exercises and a gradual return to activity. Several of the patients have been able to return to rather strenuous athletic participation. One of our patients, against advice, was able to play first-string basketball at a Minnesota college three months after the laminectomy. Another patient has been able to satisfactorily play Big Ten football and has had no complaints after hard contact of line work.

Conclusion

In conclusion, I feel we should remember that true intervertebral disc lesions occur fairly frequently in the teenage group. Their treatment is chiefly conservative and only a small percentage require eventual laminectomy. The patients' presenting complaints and physical findings differ very little from adults. The prognosis in the patients not requiring laminectomy is rather good and in those requiring laminectomy the determining factor is the pathologic finding at operation. In cases in teenagers with complete separation of free fragment discs the prognosis is probably better than in adults with similar lesions.

THE FAMILY PHYSICIAN AND PUBLIC HEALTH

Health departments have traditionally worked with the full co-operation of the medical profession. The family physician is the front line of any public health endeavor. In order for a community health program to succeed, the practitioner must give full co-operation and active rather than passive support. Experience has shown that the more extensive the public health program a community enjoys, the greater the demand made by the public on services not only for the treatment of illness but also for health supervision and for preventive services.—Vlado A. Getting, M.D., J.A.M.A., Sept. 26, 1953.

RADIOACTIVE ISOTOPES IN DIAGNOSIS AND TREATMENT

CHARLES A. OWEN, JR., M.D.
Section of Clinical Pathology
Mayo Clinic and Mayo Foundation
Rochester, Minnesota

NATURALLY occurring radioactive isotopes, such as radium and radon, have served medicine usefully for several decades. The discovery, in 1933, by Joliot and Curie that stable elements could be converted into artificially radioactive ones opened up undreamed possibilities that physicians are only beginning to realize.

The unstable (radioactive) isotopes or variants of naturally occurring elements achieve stability by means of reorganization of their nuclear structure. This reorganization is accompanied by emanations of various types, which include alpha, beta and gamma rays. As an example, one radioactive isotope of iodine (I^{131}) emits both beta and gamma rays; in so doing, its chemical properties are transmuted from those of iodine to those of xenon. The superscript number is used to identify the isotope, thus, I^{127} is the normal, stable form of iodine, while I^{131} is an isotope which weights 4 atomic units more. The various radioactive isotopes undergo nuclear reorganization at speeds varying from fractions of a second to billions of years. By convention these rates are expressed as the time required for the element to undergo half its radioactive degradation; thus, I^{131} has a "half life" of 8 days. In honor of Marie and Pierre Curie, codiscoverers of radium, the unit of radioactivity is the curie, which is approximately equal to the emanation from 1 gm. of radium. A thousandth and a millionth of a curie are designated as a "millicurie" (mc) and a "microcurie" (μc).

Radioactive isotopes are being used in medicine for therapeutic purposes and for tracer studies. The goal in treatment is to find an isotope with the following characteristics: (1) some degree of predilection for a certain organ or diseased cell, (2) sufficient strength of radiation to kill the diseased cells without serious injury to the patient as a whole; (3) no chemical toxicity and (4) a short half-life, so that the hazard of radiation is limited to days or at most weeks. To be able to concentrate a radioactive substance within a diseased portion of the body affords a means of intimate, continuous radiation without the interposition of normal tissues between the source and the target zone. Iodine, for example, tends to concentrate within the acinar epithelial cells of the thyroid gland; since these cells are unable to distinguish between stable I^{127} and radioactive I^{131}, administration of the latter leads to an internal source of radiation within hyperplastic or malignant thyroidal cells.

Radioactive colloidal gold (Au^{198}) settles out on pleural and peritoneal surfaces, affording a method of treatment of metastatic malignant lesions on these surfaces. Although cures by this method of treatment are rare, the relief of pain and diminution of effusion are often gratifying. Au^{198} may be injected directly into malignant tumors of the prostate, cervix or skin. Radioactive phosphorus (P^{32}), like its stable isotope, inclines toward regions of rapid growth, including bone marrow. This material lends itself readily, therefore, to treatment of the overactive erythropoiesis of polycythemia vera.

The other and perhaps more important medical application of radioisotopes is in the tracing of movements of elements within and between compartments of the body. The advantages of this method over direct chemical analyses are twofold. While one can measure chemically with precision the concentration of iodine (I^{127}) down to a few billionths of a gram per milliliter, one can detect radioiodine (I^{131}) in solutions still more dilute by a factor of several million. Secondly, if the radioactive element should emit gamma rays, sensitive counters can detect the element from outside the intact body, because the gamma rays readily penetrate several inches of tissue and pass into the neighboring atmosphere. When a detector of radioactivity is placed over the thyroidal region of the neck and radioiodine is given intravenously, one can measure accurately the rate with which I^{131} concentrates in the thyroid, as well as the absolute amount extracted from the blood. Both these values are proving to be diagnostically useful in disease of the thyroid.

Many other diagnostic uses of radioisotopes, based on measurement of internal radioactivity from outside the body, are being investigated. These include: (1) localization of tumors of the brain, retina, breast and liver; (2) demonstration of block of the spinal canal; (3) evaluation of extravascular concentrations of blood; (4) estimation of the vascularity of skin grafts and (5) measurement of cardiac output and circulation time.

When samples of fluids or tissues can be removed from the body, more refined radioisotopic techniques become available. These methods often have an added meaning when chemical or biologic assay of the stable chemical is made along with determination of radioactivity. Globulins labeled radioactively are being studied by immunologists. Curiously enough, these studies are yielding results somewhat different from those obtained by labeling the same proteins with azo dyes. When serum albumin tagged with radioactive iodine is injected intravenously and allowed to mix thoroughly, the resulting calculated volumes for plasma and whole blood are as accurate as the results of dye methods and are simpler to obtain. Erythrocytes may be tagged with a variety of radioactive elements, which enables one to determine erythrocytic volumes and to estimate the longevity of these cells in various hemolytic states.

To the biochemist and the physiologist, radioactive substances are becoming indispensable accessories, particularly since the radioactive isotope of carbon (C^{14}) has become generally available. Even the bacteriologist has at his disposal bacteria in which radioactivity is incorporated from their nutrient medium.

Since the radioactivity of these various isotopes is potentially dangerous to both the patient and the investigator, only those familiar with the hazards are allowed by the Atomic Energy Commission, which is the sole agency authorizing their use, to handle radioisotopes. By virtue of his training, the radiologist is familiar with the benefits and dangers of radiation; he should be an integral part of the team to handle the isotopes. With expanding use of isotopes in diagnostic procedures, the clinical pathologist will find himself also a member of the team.

* * * * * *

This is the thirteenth in a series of editorial reports sponsored by the Minnesota Society of Clinical Pathologists and designed to foster closer relationships between the practicing physician and the pathologist.

The use of radioactive isotopes again emphasizes, as have several other of these reports, the ever-increasing role played by the laboratory physician in the modern practice of medicine. Although most physicians will not actively handle radioactive materials, they should be aware of the potential hazards associated with such factors as disposal of radioactive excreta from patients who have received radioactive isotopes.

RESIDENCY IN ANESTHESIOLOGY

The Army Medical Service residency program in anesthesiology will be increased in term to three years beginning July 1, 1954. to give candidates additional training, it has been announced by Major General George E. Armstrong, Surgeon General.

The new plan provides for the two years of clinical training required for American Board of Anesthesiology certification and an additional year devoted to research and development training co-ordinated with the basic sciences in anesthesiology.

According to the new plan, selected Medical Corps officers will spend their first year of the three-year residency at Walter Reed Army Medical Center, Washington, D. C., where they will receive fundamental clinical training.

The second year will be presented at the Army Medical Service Graduate School, Walter Reed Army Medical Center, Washington, and will be devoted to research and development.

The last year of residency will be spent at one of four Army hospitals and will present the candidates with a summation of training with clinical and teaching experience. The four hospitals to be utilized in the program are: Brooke Army Hospital, Brooke Army Medical Center, Fort Sam Houston, Texas; Fitzsimons Army Hospital, Denver, Colorado; Letterman Army Hospital, San Francisco, California; and Walter Reed Army Hospital, Walter Reed Army Medical Center, Washington, D. C.

President's Letter

DOCTOR AND PATIENT

The relationship of the doctor to his patient and the resulting public opinion of the profession as a whole should be uppermost in the minds of all doctors these days. In recent months, the entire medical profession has withstood many unpleasant attacks which have actually stemmed from the unethical practices of a small minority of practitioners.

Naturally, such articles bordering on the sensational, make excellent copy and rate high readership for both the author and the publications in which they appear. Medicine and medical news have reached a high point in lay readership, and as a consequence, any material of this nature is fair game for writers, and often results in unnecessary and unfair exploitation of the facts. It is unfortunate that only the substandard aspect of medicine should gain such notoriety.

On the official level, American medicine has reacted in various ways, ranging all the way from bitter indignation to complete disregard. Letters have been written to the editors, complete facts have been submitted, answering articles have been published, and verbal renunciations have been used.

However, would it be too much to ask of American medicine to revert back to the down-to-earth policy of improving its individual members' day-to-day relationships with the people who may hold some of those views—their patients? Physicians can do no better than that, to prove to the American people that they are conducting their practices on the highest possible level.

And, medicine is doing a job of policing itself on such matters. Medical organizations have established mediation boards with the express purpose of culling out those who infringe on medical ethics, and also to study any grievance against a member.

Another comeback to the sensational article writers has come to light recently. It is interesting and gratifying to see that some publications have printed articles pointing out this very fact—that the entire profession should not be condemned because of the unfortunate actions of a few.

With both writers and advertisers contributing, it is to be hoped that increased mutual good will and understanding will develop between doctors and patients.

Among the most recent items of this new pattern showing what American practitioners are really like are these: the January 11 issue of *Life* magazine carried an advertisement on "How to Select a Family Doctor;" the same ad appeared in the February 6 issue of the *Saturday Evening Post*, in February's *Woman's Home Companion,* February's *Parents Magazine* and in February's *Today's Health;* the November 1953 issue of *Better Homes and Gardens* carried an article entitled "When You Need a Doctor in a Hurry—What Will You Do?"; *Rotarian* of December, 1953 ran an article called "Don't Kill Your Doctor;" and *Look* of November 17, 1953 published a piece on how "Mississippi Trains Its Own Country Doctors."

These are only a few of the recent articles and advertisements appearing in national publications, which emphasize the positive side of American medicine. It is hoped that as a result of less sensational and more factual printed material, more and more people will realize that not all physicians adhere to the described unethical practices, and that the profession, as a whole, cannot be rightfully judged by the actions of the minority.

POLIO VACCINATION WITH A PRAYER

WE HAVE rejoiced with the recently announced prospects of a control for poliomyelitis. The series of discoveries from those of John F. Enders culminating in those of Jonas E. Salk reads like a streamlined version of Microbe Hunters. We delight in the thought that the National Foundation for Infantile Paralysis may have been instrumental in hastening these discoveries by many years. We want ever so much to have this scourge of mankind under control as soon as possible and at the same time see to it that those responsible get the proper recognition. However, as physicians, we soon learn after a continuous series of disillusionments to modify our immediate reaction "This is it!" to "This could be it."

In Minnesota, the State Board of Health, as the official public health agency of the state, is in the position where it must assume responsibility for the program of vaccination against poliomyelitis in 1954. The Board has given careful and continuing consideration to this matter since first approached. Several meetings have been held on the program with members of the State Polio Planning Committee; with the Council and other representatives of the Minnesota State Medical Association; with officials of the National Foundation for Infantile Paralysis; and consultation has been had by telephone and correspondence with scientists in other states, Canada, and Washington. The State Board, in addition, called together a special scientific advisory committee which met on January 20 to advise the board as to recommended procedures in the light of the latest available information. Developments since then have likewise been fully considered.

We wish to commend most highly the State Board for its cautious and yet complete approach to this important problem. The medical profession, as a group, has been constantly kept in the picture, and the advice of the best scientists in this field has been obtained. Everyone concerned has shown a desire to give wholehearted endorsement and support to the program of successful polio vaccination in Minnesota; yet throughout, care is being exercised to ensure complete safety of the procedure and the collection of sound data on which to evaluate the effectiveness of the vaccine. When the time comes for final plans, the medical profession will be glad to do its part.

ROUTINE CHEST ROENTGENOGRAMS IN PRIVATE HOSPITALS

IT is a matter of established fact that the most fertile field for the discovery of pulmonary lesions lies in the routine roentgen examination of the chests of patients being admitted to hospitals. It is also unquestionably a fact that hospitals should take all steps possible to protect their employes and patients from infectious tuberculosis. This is because of the responsibility, both moral and legal which the hospital must take. Therefore, it is of the utmost importance that hospitals make this relatively simple examination of all persons becoming associated with them, not only as a patients but also as employes or attendants in any capacity.

Most of the hospitals in Minnesota will be forced to make necessary adjustments for the examinations in their present accommodations. It is important that the examination unit be in as close proximity as possible to the admission area. The greater the distance between these departments the more difficult it is to obtain roentgenograms of patients, particularly of those admitted under trying circumstances, such as persons injured or those in labor. New hospital buildings being planned or constructed may easily make provisions for chest roentgenograms near or adjacent to the admission office. As a matter of fact, it seems that new hospital plants are now being arranged with the roentgen department on the entrance floor for greater convenience.

The type of routine roentgen examination does not have great significance. The method of making a roentgenogram in only one projection can be regarded as no more than a survey regardless of whether miniature or standard sized films are used. In general, it seems that hospitals of 150-bed capacity or less could best use 14 x 17-inch films made in the established roentgen department. On the other hand, larger institutions should be economically better off by investing in a photoroentgen unit. These larger institutions would eventually repay the investment in a photoroentgen unit merely in the saving made on the examinations of new employes and the interval follow-up examinations of these employes.

The Minnesota Radiological Society has recommended that a charge of $1.50 be made to patients being admitted for photofluorograms and that a $4.00 charge be made for 14 x 17 films. These charges are in effect in those institutions employing either method in the Twin Cities. It is felt that these charges make the procedure self-supporting, which is no more than proper. A profit would probably defeat the purpose of the survey. On the other hand, the findings are of sufficient value to the individual being examined to make it worth his while to underwrite his share of the money and effort being expended by those responsible for the project.

It is apparent that processing of the films can best be done in the established roentgen department. It does not appear that there is any hospital in Minnesota sufficiently large to justify the establishment of a separate processing unit. It is cheaper and easier to provide the necessary material for developing and subsequent handling of film to last over a twenty-four-hour period than it is to construct and maintain separate facilities for this work. This also eliminates the need for a self-sustaining staff for the unit. Technicians, often students, can be employed to operate examination units in the larger institutions from 2 to 5 or 6 p.m. daily when most hospital admissions take place. During this time, these employes can also make roentgenograms of the chests of those persons admitted but not examined during the previous twenty-four hours. During the remainder of each day, the admitting office personnel can be made responsible for the procedure. It is a simple matter to train any reasonably intelligent person in the technical aspect of making a chest roentgenogram.

The keeping of records should be as uncomplicated as possible, as long as the records accomplish the primary purpose of the survey, namely—to protect patients and employes from infectious tuberculosis. The hospital *does* have the right to see to it that infectious tuberculosis be recognized or ruled out in any given chest lesion. Also the hospital has the right to insist that any necessary precautions be carried out when infectious tuberculosis is suspected. Beyond that, the individual members of the staff and medical organizations at the staff level and upward are responsible for subsequent diagnosis, observation and treatment of patient having lesions which are non-infectious.

Simplicity of record keeping saves time, money and personnel. It reduces the research value of the project. However, research should be left primarily to subsidized institutions. Hospitals depending for their support upon private fees are obligated to use those fees for private benefits. If the private hospital were to become engaged in a large scale follow-up program, elaborate records would become necessary. Keeping the fact in mind that the survey is made to discover infectious tuberculosis, a long-range follow-up program does not seem to be the responsibility of a private hospital. All positive findings should be reported to local or state health authorities for subsequent action. Such a plan could add greatly to the overall value of the projects under discussion.

It should be of interest to record briefly the most important findings in an admission survey made over a three-year period in one Minnesota private general hospital.* During the three years 17,790 patients had photofluorograms. The interpreter noted 2,307 positive findings. Twenty-six of these patients, previously unsuspected of having disease, are now undergoing institutional treatment for pulmonary tuberculosis. Three hundred sixteen are being observed or treated privately for suspected tuberculosis. Twenty-nine primary thoracic tumors were discovered, and twenty-one metastatic pulmonary lesions came to light. Eleven "coin" lesions were found, the majority of which are known to be static by reference to previous examinations or by subsequent examinations. Exact classification of these eleven lesions cannot be given because they have not been removed. Cardiac and aortic abnormalities accounted for 629 positive findings. Other findings, such as large calcified primary complexes, adhesions, anomalies, scoliosis, old fractures, et cetera, of doubtful or no clinical significance, accounted for most of the remaining positive reports. However, eighty pleural effusions (mostly congestive), two cases of silicosis, a pulmonary cyst and other interesting conditions were seen.

A routine admission film is unquestionably of great value in the study of general hospital patients. In addition to its primary purpose, it frequently provides a short-cut to the final diagnosis and disposition of the patient. The total time of hospitalization is often reduced by a more speedy diagnosis. Discovery of pertinent findings not related to the reason for hospitalization may be made. We believe that routine chest examinations are more important in the detection of disease than routine urinalysis and blood studies.

---

*St. Joseph's Hospital, St. Paul, Minnesota.

J. P. Medelman, M.D.

ROUTINE X-RAYING OF PATIENTS ADMITTED TO GENERAL HOSPITALS

THE x-raying of all admissions to general hospitals is an essential element of the tuberculosis control program. Most reports of hospital admission x-ray screening programs cite the discovery of unsuspected cases of disease, and relate an over-all percentage yield of tuberculosis that is higher than that found in the screening of general population groups. This is quite to be expected, for patients coming to hospitals are generally older people, and people with chronic diseases and vague symptoms. It is this group that usually participates poorly in general population surveys, which are directed at finding unsuspected disease in the apparently healthy person. Moreover, since some heart conditions and other chest disorders, as well as tuberculosis, can be detected by admission x-rays, good medical practice would seem to require that chest x-rays be taken on admission as routinely as blood tests and urinalyses.

The program of x-raying all hospital admissions represents an investment that pays multiple dividends to patients, hospital and community. Often, treatment for a previously undetected disease is received by the patient at an earlier date as a result of discovery by admission x-ray. In addition, the risk of infection within the hospital from an unsuspected case of tuberculosis is minimized for fellow patients, staff and personnel. And lastly, the chain of tuberculosis infection within the community is broken when a previously unsuspected case of tuberculosis is detected by the admission x-ray and brought under public health supervision.

Minnesota deserves congratulations on having one of the lowest tuberculosis death rates in the world in 1952. In fact, tuberculosis has not been among the ten leading causes of death in the state for the past three years. The achievement of this enviable record comes as no surprise, in view of Minnesota's vigorous execution of a progressive tuberculosis control program.

It is also gratifying to know that approximately forty of Minnesota's hospitals are routinely x-raying all admissions and that this program has the endorsement of the Minnesota State Medical Association, the Minnesota Department of Health, and the Minnesota Tuberculosis and Health Association. The fact that more than 2,000 previously unreported cases of tuberculosis are still being found each year in the state, emphasizes the necessity of intensifying case-finding efforts. Like the widely accepted techniques of surveying apparently healthy population groups, of x-raying residents and employes of mental and penal institutions, and of examining contacts and suspects, case-finding among hospital admissions is another extremely effective device which merits application. The general hospitals in Minnesota that do not routinely x-ray their patients on admission are urged to explore the possibilities of this important aspect of a tuberculosis control program.

Although x-raying all admissions presents the already heavily burdened general hospital with additional administrative and financial problems, many of these problems can be readily solved; the costs of the service are moderate, and the rewards are many. Coupled with recent improvements in treatment, the routine x-raying of some 13 million Americans entering general hospitals each year, would certainly bring us closer to the control of tuberculosis.

R. J. Anderson, M.D.

Doctor Anderson is Chief, Division of Chronic Disease and Tuberculosis, Public Health Service, U. S. Department of Health, Education, and Welfare.

MATERNAL MORTALITY SURVEYS

NATIONAL mortality rates were high and showed little change from 1915 to 1930. The average rate was 7.0 maternal deaths for every 1,000 live births. During this same period in Minnesota there was an average of 5.2 maternal deaths per 1,000 live births. Prior to the enactment of the Shepard-Towner Act of 1921 maternal health activities were carried on by a few state health departments or state medical associations. In 1917, the New York Academy of Medicine first became interested in the problem of puerperal mortality because death rates from puerperal causes had remained stationary while death rates from other preventable causes had been steadily declining. Our Division of

Child Hygiene, now known as the Section of Maternal and Child Health, was established by the Minnesota Department of Health in 1922. The Maternal Health Committee of the Minnesota State Medical Association was first appointed in 1936.

Because there was little change in the national maternal mortality rates for the previous ten years, the Obstetric Advisory Committee of the U. S. Children's Bureau, of which Dr. Fred L. Adair of Minnesota was a member and later the chairman of the American Committee on Maternal Welfare, in 1926 presented a plan of study of all puerperal deaths to be conducted in certain states in 1927 and 1928. Studies of maternal mortality based on death certificates were known to be insufficiently detailed to give an accurate picture of the situation. Accordingly, the study was to be carried out by means of personal interviews with the physicians attending all deaths from puerperal causes. The study was made in fifteen states, including Minnesota, at the formal request of each state medical society. The interviews were carried out by physicians on the staff of the State Boards of Health who visited the attending physician or midwife as well as the hospital concerned. The report was written under the guidance of the Obstetric Advisory Committee and was the first intensive and accurate study from which valid conclusions could be drawn. It furnished the impetus for subsequent studies which led to the establishment of maternal health committees in various parts of the country.

In 1930, the New York Academy of Medicine through its Committee on Public Health Relations began a detailed "study of the phases of the public health problems of obsetrics as they affect New York City." It was patterned along the lines of the survey made by Adair and his associates—the so-called "Fifteen States Study" and used the same questionnaire so that satisfactory comparisons would be possible. The three-year study was made in co-operation with the Department of Health of New York City and the Obstetrical Society of New York. The final conclusion of this study stated, "The hazards of childbirth in New York City are greater than they need be. Responsibility for reducing them rests with the medical profession." Coming from the medical profession itself and pointing out that two-thirds of deaths due to childbirth could be prevented if the care of the woman had been proper in all respects, the report aroused intense controversy and was followed by a storm of lay and medical criticism. Its publication, however, led to the formation of maternal mortality committees in many local groups and hospitals. A committee on maternal welfare was established by the Philadelphia Medical Society which is still actively functioning. Shortly afterwards such committees were organized by county medical societies of New York City, Cleveland, Boston and other areas.

This activity on the part of the medical profession in co-operation with public health authorities has been a major factor in the marked and continued decline in maternal mortality. Other factors that accelerated the rate of decline included better undergraduate training of physicians, increased postgraduate training and refresher courses in obstetrics, increased rate of hospitalization and more adequate hospital facilities and services, widespread use of chemotherapeutic agents and antibiotics, and increased availability and use of blood. In addition, public health measures such as the education of the public to the importance of early and adequate prenatal care as well as good obstetric care has played a significant role.

Information from the state health departments of all states and territories in 1951 indicated that maternal mortality surveys were being carried out in nineteen states and the District of Columbia. A number of larger cities also carry on similar studies, including Philadelphia, New York City, Syracuse, San Diego, and others. Twelve states send questionnaires to physicians and hospitals. A few limit their surveys to the information available on death certificates. Only eight states, including Minnesota, make a thorough investigation by the personal visit of trained obstetricians, considered by most authorities to be the only effective means of obtaining accurate and worthwhile data. Within the past year the Wisconsin State Medical Society in co-operation with the Wisconsin Department of Health has instituted a similar study. During the past two years the Minnesota Maternal Mortality Committee has received requests for detailed information on the operation and procedures of the study from eight state medical and obstetrical societies.

The first statewide maternal mortality study in Minnesota was carried out from July 1, 1941, through June 30, 1942, by the Maternal Mortality Committee of the Minnesota State Medical As-

The Dean's Page

THE LYON LABORATORIES

On February 11, the University of Minnesota will dedicate the new medical building which is being named in honor of the late Elias Potter Lyon, Dean of the Medical School from 1913 to 1936.

This building, which joins Millard Hall and the Anatomy Building along Washington Avenue, contains four stories and a basement. The ground level is left open for a passageway into the court of the Medical School quadrangle.

The first floor of this building is divided into laboratories for histo-cyto-chemical research and is under the direction of Dr. David Glick, a national leader and authority in this field of work. The funds for this unit were provided by the National Heart Institute in order to increase facilities for research and for the training of personnel in this new and important field of micro-chemistry.

The second and third floors are assigned to cancer biology and provide facilities for the work of Dr. John J. Bittner and his associates, Dr. Carlos Martinez, Dr. Marthella Frantz, etc. One of these floors is devoted to laboratories, while the other houses thousands of pure strain inbred mice. Dr. Bittner is internationally known for his discovery of the "milk factor" in the development of hereditary mammary cancer in mice, as well as for other contributions to knowledge about genetic factors in cancers of mice. For this work Dr. Bittner recently received an award, the first made under a special bequest, from Middlesex College Hospital in London for the most important contribution to cancer research made anywhere in the world. The funds for the construction of these two floors were provided by the Minnesota Division of the American Cancer Society.

The fourth floor is devoted to bio-physics, a field of basic medical research of constantly increasing importance. Laboratories on this floor are utilized by Dr. Maurice Visscher and others in the Department of Physiology, and Dr. Karl Stenstrom and his colleagues in Radiation Therapy. The funds for this unit were provided by the National Cancer Institute.

The basement, as soon as funds for its completion can be obtained, will be devoted to air-conditioned animal quarters and associated research laboratories. This will enable us to use for other purposes the roof-house of Millard Hall which has been ill-suited and unsatisfactory for animal quarters.

Altogether this new building provides the Medical School with some long and urgently needed facilities for basic medical research. We invite the physicians of the state to visit this unit when they have an occasion or opportunity to come to the campus.

FTC FIGHTS DECEPTIVE ADVERTISING FOR HEALTH INSURANCE

A nationwide investigation into objectionable and deceptive advertising for hospitalization and medical care insurance has been initiated by the Federal Trade Commission. According to a recent issue of the Washington Report on the Medical Sciences, trade practice rules were promulgated by FTC in 1950, but this is the first large scale inquiry of its kind to be undertaken by the Commission.

Assistance of businessmen, state authorities and the public has been requested by Chairman Edward F. Howrey. Among the cases of alleged violations of trade rules already in FTC's hands are several which it received recently from William Langer, Republican senator from North Dakota, who is chairman of the Senate Judiciary Committee.

According to the Washington Report, "an estimated 800 health and accident companies, relying chiefly on advertising and mail-in coupons for their business, are in this highly competitive field today. There were fifty in 1925. In 1952, net premium payments totaled nearly $1.9 billion, which was an increase of 206 per cent over 1946."

CLAMOR FOR SECURITY REPORTED BY MRS. HOBBY

According to Mrs. Oveta Culp Hobby, secretary of the Department of Health, Education and Welfare, "the American people want more economic security."

Mrs. Hobby spoke to the third annual American Assembly recently, meeting in New York to discuss economic security problems. Mrs. Hobby pointed out that Federal Social Security was one of three foundations for the economic security of the individual, supplementing industrial pension and insurance plans and individual savings. She remarked that the present high rate of individual savings indicated that Social Security had not affected the incentive of individuals to provide for their own future, insofar as they are able.

According to a recent news issue from the Research Council for Economic Security, which reported the *New York Times*' account of the meeting:

> "It was stated that the conferees were in general agreement that the American people wanted more Social Security because 'they realized increasingly how little economic independence they had as individuals.' The consensus of the panels was that the average American had a feeling of insecurity and that such anxiety was justified by past experiences and the complexities of contemporary life. These factors, rather than a softening of national fibre, are responsible for concern over social security programs, the participants are reported to have found."

HOUSE, TOO, LOOKS AT SOCIAL SECURITY

Before the opening of the second session of the 83rd Congress in January, the fact-finding hearing on the Social Security program opened with much less flourish. The House ways and means subcommittee hearings were the preliminary to what promises to bring a very explosive battle over the whole philosophy of the old-age and survivors-insurance system. Evidences of this coming battle have already been seen in political events of the past month or so.

No matter how hot and heavy the battle, the committee, under Representative Carl T. Curtis of Nebraska, brought out some very useful and interesting information about Social Security costs and possible extension of coverage.

President Eisenhower has repeatedly asked for extension of Social Security to cover about 6,500,000 more persons, including self-employed farmers, domestic servants not now covered, and professional persons, with optional coverage to be provided for an estimated 4,000,000 more, including clergymen and employes of state and local governments.

Present System Studied

The Committee spent considerable time studying the present system of Social Security, and brought to light some interesting facts and figures regarding the large amount of old-age-benefit dollars going abroad.

According to a recent issue of *Insurance Economics Surveys,*

> "Records show that the $13,000,000 in Social Security benefits paid to beneficiaries abroad in 1952 exceeded the amount going to beneficiaries in 12 states here at home. These states were listed as Arizona, Delaware, Idaho, Montana, Nevada, New Mexico, North Dakota, South Dakota, Utah, Vermont, Wyoming, and Mississippi, mainly agricultural states where farmers are not covered by Social Security.
>
> "It also brought out that such beneficiaries abroad are in a position to earn unlimited amounts on the side, whereas beneficiaries here forfeit their benefit payment if they earn more than $75 a month. Social security authorities admitted that they were stumped in finding a means of enforcing that stipulation abroad."

The American Medical Association has taken a stand opposing the inclusion of the medical profession in the extension of social security.

PRESIDENT PRESENTS HEALTH PROGRAM

President Eisenhower's State of the Union message to Congress brought forth many statements on general Administration policy on important medical matters. In summary, this is what he said:

Socialization of Medicine: "I am flatly opposed to the socialization of medicine. The great need . . . can best be met by the initiative of private plans. But it is unfortunately a fact that medical costs are rising and already impose severe hardships on many families. The federal government can do many things and still avoid the socialization of medicine."

Research: "The federal government should encourage medical research in its battle with such diseases as cancer and heart ailments, and should continue to help states in health and rehabilitation."

Hill-Burton Program: "The present . . . act should be broadened to assist in the development of adequate facilities for the chronically ill . . . of diagnostic centers, rehabilitation facilities and nursing homes."

Reinsurance of Health Plans: "The war on disease . . . needs a better working relationship between government and private initiative. . . . A limited government reinsurance service would permit the private and non-profit insurance companies to offer broader protection to more of the many families which want and should have it."

Rehabilitation: "The program for rehabilitation of the disabled especially needs strengthening. . . . This program presently returns each year some 60,000 handicapped individuals to productive work. Far more disabled people can be saved each year . . . if this program is gradually increased."

Military Dependents: "Pay alone will not retain in the career service . . . the necessary numbers of long-term personnel. I strongly urge, therefore, a more generous use of other benefits important to service morale. Among these are more adequate living quarters, and medical care for dependents."

Medical Tax Deductions: ". . . we propose more liberal tax treatment for dependent children who work, for widows or widowers with dependent children, and for medical expenses."

Veterans: "The internal reorganization of the Veterans Administration is proceeding with my full approval. When completed, it will afford a single agency whose services, including medical facilities, will be better adapted to the needs of those 20 million veterans to whom the Nation owes so much." (There was no further reference to VA in the address.)

Social Security: "I ask that this extension (to 10,000,000 more persons) soon be accomplished. This and other major improvements . . . will bring substantial benefit increases and broaden the membership of the insurance system, thus diminishing the need for Federal grants-in-aid. . . ."

PLAN WOULD REINSURE VOLUNTARY HEALTH INSURANCE

The reinsurance of voluntary health insurance plans, referred to above, was asked of Congress by the Administration. The heart of the program probably would be a corporation set up with a federal appropriation for its original working capital. Once under way, its operations would be supported by payments from the member health insurance organizations of a percentage of their gross income from premiums. In some respects, it would be similar to the Federal Deposit Insurance Corporation for bank deposits.

According to a recent issue of the AMA Washington Letter, the reinsurance corporation device follows the general lines of the 1950 Wolverton bill. Mr. Wolverton was then a minority member of the House Interstate and Foreign Commerce Committee which must handle such legislation. Now he is chairman and in a position to effectively push his idea. The Eisenhower plan is understood to include the following three major objectives of the Wolverton bill:

"1. Make it possible for health insurance plans to offer catastrophic or comprehensive coverage by having the federal corporation pay one-third or three-fourths of each survivor's claim in excess of $500 or $1,000.

"2. Make it possible for—or even require—the plans to offer coverage to individual subscribers.

"3. Require all participating plans to scale the cost of premiums in relation to family income. Families at the $5,000 or $6,000 level would pay the maximum, with those earning less paying less."

Other pertinent factors involved in this reinsurance plan are:

"Participating groups would pay about 2% of gross premiums collected to support federal corporation. . . . A limit would be placed on out-state subscribers. . . . Also a limit on over-the-schedule payments to physicians or hospitals. . . . Benefits would have to be clearly defined and meet standards set by the corporation. . . . Patients would have to be allowed free selection among participating hospitals and physicians. . . . Every licensed physician would be eligible to participate. . . . The Wolverton plan excludes commercial companies but the present administration program would admit them."

OREGON MEDICAL SOCIETY OPPOSES REINSURANCE

In line with the American Medical Association's opposition to the Administration plan for reinsurance of voluntary non-profit health insurance, the Oregon State Medical Society has already passed a resolution against such a proposition.

Quotes Supreme Court

Basing its opposition on the belief that reinsurance would actually subsidize the plans and therefore bring federal control, the Oregon organization states:

"The administration has declared that its proposed subsidies to voluntary health insurance plans do not involve 'government regimentation and control' in spite of the fact that the United States Supreme Court (1942) has declared that 'it is hardly lack of due process for the government to regulate that which it subsidizes.'"

The resolution further declares:

". . . the intervention of the federal government in the form of subsidies or otherwise in the operation of the voluntary health insurance plans is unwarranted in the face of the outstanding record of these plans which already have extended their benefits satisfactorily to increasingly large segments of our people, and are increasing the scope of their benefits as rapidly as is consistent with financial soundness. . . ."

Woman's Auxiliary

RAMSEY COUNTY REPORTS ON PROJECTS

The Women's Auxiliary to the Ramsey County Medical Society has completed several major projects since the beginning of activities for the year last fall.

The doctors' wives co-operated with the Fourth District Minnesota Nurses' Association in sponsoring panel discussions in various high schools throughout Saint Paul for nurse recruitment. Doctors' wives sat in on many of the panels, and aided in the transportation of speakers to and from the meetings. Mrs. Wallace Gleason served as chairman.

At the Board meeting in November, 1953, the Auxiliary made sixty cancer dressings.

The Ramsey auxiliary also co-operated in the annual Christmas Seal sale, helping to staff downtown booths with thirty-eight women. Total sales were $136.22. The auxiliary aided in the sponsorship of the annual tuberculosis essay contest among Saint Paul school children. Mrs. George Snyder served on the judging panel. The contest was won by Barbara Tauer of St. Joseph's school and by Ray Blacik of St. Agnes' school.

The January meeting was held at the Saint Paul College Club on January 25. Mrs. M. D. Hilker served as program chairman. The program emphasized civil defense and featured an excellent discussion by Mr. Donald Wood, executive secretary of the Association of Twin City Hospitals. Two films were shown: "One Survival" and "Emergency Action to Save Lives." At this meeting, the winners of the tuberculosis essay contest appeared to read their essays and also to receive $10 gift bonds from the Auxiliary.

AUXILIARY MEETS IN CROOKSTON

The Women's Auxiliary to the Red River Valley Medical Society met at the home of Mrs. D. E. Stewart, Crookston, Friday evening, January 8, 1954. The meeting followed a dinner at the Hotel Crookston with the Red River Valley Society. It also occurred on a night of wind and snow which forced many out-of-town visitors to remain in Crookston overnight.

Mrs. Stewart reported on subscriptions to *Today's Health,* and Mrs. J. F. Norman, of Crookston, gave the report on current legislation. Mrs. Norman is legislative chairman of the group.

Mrs. C. L. Oppegaard told about the regional meeting of the State Auxiliary organization at Detroit Lakes, and Mrs. A. R. Reff, of Crookston, reported on the orthopedic clinic held in Crookston in October.

Among out-of-town guests were Mrs. G. A. Sather, of Fosston; Mrs. C. L. Roholt, of McIntosh; Mrs. Clifford Stadem, of Twin Valley, and Mrs. B. R. Kinkade, of Ada.

MEDICAL STUDENT ENROLLMENTS

Says the *Journal of the American Medical Association*† disclosing the 53rd annual report on medical education of its Council on Medical Education and Hospitals, "enrollments in the country's 72 medical and seven basic science schools during 1952-53 totaled 27,688, or 2.3 per cent more than the 27,076 enrolled during 1951-52. The 5,668 students graduated during the last year exceed by 279, or 4.4 per cent, the previous record established in 1947, when at the termination of the wartime accelerated program several schools graduated more than one class. The estimated number of graduates for 1953-54, based on enrollments reported for senior classes in schools, is even greater—6,831." There was, however, a slight decrease in the size of the entering freshman class for the first time in five years—7,425, or 16 less than the record class of 1952-53.

In addition to those regularly enrolled as full-time students of medicine, medical schools had enrolled a total of 140 part-time and special students working toward an M.D. degree, and 407 students in internships that were a part of the degree requirements of the medical schools at which they were educated. There was also a total of 1,734 students from the United States enrolled in 72 foreign medical schools, located in 22 different countries.

There were 1,463 women in medical and basic science schools during 1952-53, eight less than last year, the report said. The women comprised 5.3 per cent of all students, as compared with 5.4 per cent last year. Women in freshmen classes totaled 399, against 394 last year. They constituted 6.1 per cent of all applicants to medical schools this year, compared with 5.6 per cent last year. The actual number of women graduates increased slightly—363, or 5.5 per cent of the total, as contrasted to 351 last year. The record number of women graduates—612, was set in 1949.

A total of 715 Negro students, 2.6 per cent of all enrollments, was reported.

The number of veterans enrolled in medical and basic science schools declined for the second year. There were 7,942 veterans enrolled, comprising 28.7 per cent of the total student body, as compared with 11,436, or 42.2 per cent, last year. There were 36 women veterans.

For the fourth consecutive year, the number of applicants for admission to medical schools continued to decrease, the report disclosed. During the year 1952-53, 16,763 individuals applied for admission, a decrease of 3,157 from 1951-52, and 5,516 less than the number who applied in 1950-51.

"This report has emphasized in recent years that the difficulty of gaining admission to medical schools has been grossly exaggerated," it was stressed.

"The statistics presented here amply confirm this exaggeration. The situation in the past year, when there were 2.6 applicants for each place in medical schools, was approximately comparable to the year 1929-30 when there were 2.6 applicants for each available place.

"One major factor is the disappearance of the large backlog of veterans who completed their premedical training following the termination of World War II. Another factor, one that is certain to cause serious concern among medical educators, is the sharp decrease in the number of applicants with superior academic records.

"While, again, one can only speculate as to the cause, it seems likely that this drop is in no small measure due to increasing competition for such talent from other professional fields."

Medical faculties and medical students alike show a continuing interest in education for family or general practice, the report pointed out. A high proportion of the medical schools sponsor one or more programs specifically designed to induce students to this type of practice.

The report also disclosed that physicians of this country are cognizant of the fact that medical education is a continuous process and that it is their responsibility to keep abreast of advances in the field of medicine. During 1952-53, 64,608 physicians attended 1,341 postgraduate courses.—Editorial, *New York State Journal of Medicine*, February 1, 1954.

American Medical Association

Proceedings of the House of Delegates

Clinical Meeting

St. Louis, Missouri, December 1 to 4, 1953

The Clinical Meeting of the American Medical Association's House of Delegates, December 1 to 4, 1953, in St. Louis. Missouri, was notable for an absence of the controversies and stormy debate that have characterized some of the meetings of recent years.

The delegates were chiefly concerned with the application, readjustment and implementation of programs and policies already initiated. They embarked upon few new undertakings, but to policies already adopted they gave strong support, and dissenting voices were few.

Several restatements of national policies were made for purposes of clarification. Among them were the Association's policies with respect to medical care for dependents of military personnel, also medical aspects of any program for universal military training which in the future may be passed by Congress. A new emphasis was likewise placed upon the established policy for extension of voluntary prepayment plans for medical and hospital service and the work of the Council on Medical Education and Hospitals was buttressed, in spite of some expressed dissatisfaction, in its expanded accreditation program and its participation in the so-called "Matching Intern Program."

A resolution clarifying membership status and a number of other progressive changes in the Constitution and By-Laws will be welcomed by the membership. Also the adoption of definite objectives for the new Committee on Alcoholism, initiated last year as part of the Council on Mental Health, and of a medical association policy for participating in a national blood bank.

As a result of the end of hostilities in Korea, the doctor-draft law ceased to be a major issue at this session, but the delegates approved the suggestion that Congress be asked to eliminate the draft of doctors entirely at its forthcoming session.

Dependent Policy Restated

So long as a defense army is maintained, however, the question of medical care for dependents of military personnel is likely to be an issue. Restatement of the policy laid down at the interim session in Denver was especially pointed up by consideration of the report of the Citizen's Advisory Commission on Medical Care of Dependents of Military Personnel, the so-called Moulton Commission, which favors continuing and even expanding such care by military establishments. The statement adopted by the House of Delegates declared that the recommendations of the Moulton Commission "would completely reverse the generally accepted position that civilian facilities, if available and adequate, should be utilized first and that the use of military facilities should be restricted to emergencies and to dependents overseas and in remote areas." The statement will now be sent to the Secretary of Defense, to the chairmen of Senate and House military affairs committees and to the Commission on Re-organization of the Executive Branch of the Government, the Hoover Commission. The fact that President Eisenhower in his State of the Union address to Congress subsequently asked for increased medical service for dependents of military personnel makes it certain that this issue will assume especial importance in the months to come.

The policy adopted with respect to any future program of universal military training which may be passed by Congress is in line with the stand on dependent care and with the vigorous opposition voiced at the June meeting against medical service for veterans with non-service-connected disabilities. All have as their objective the placing of definite limitations on the amount of medical service to be provided by the federal government which may otherwise soon expand to a point where the private system of medical service and the quality of care available to the public in general is seriously threatened.

Medical Students Should be Excluded

If any plans are being laid now for early adoption of universal military training, medical students should be excluded from consideration until after they are graduated from medical school, the delegates believe. Their policy also calls for pre-induction examinations and periodic check-ups during the reserve period to be performed by civilian physicians in order to avoid serious withdrawals from hard-pressed civilian medical services. It calls for rehabilitation and corrective treatment which might be found necessary in pre-induction examinations to be carried out, likewise, by civilian doctors in civilian institutions and it asks that trainees in any contemplated reserve corps be ruled ineligible for veterans' medical benefits unless their disabilities are actually connected with active military service.

The delegates proposed that a civilian board be set up nationally to insure a proper balance between civilian and military needs. In that connection, also, they approved an official request from the association that a physician be retained under the reorganization plan in the position of Assistant Secretary of Defense (health and medical). The position is held at the present time by Dr. Melvin A. Casberg.

In order to carry forward the campaign initiated by the American Medical Association last June against federal medical care for veterans with non-service-connected disabilities, with stipulated exceptions, each constituent association was urged by the delegates to create a special committee on veterans' medical service. Several regional conferences on the subject have already been held and they will be extended to all parts of the country to acquaint doctors with AMA policy, it was announced.

Membership Clarified

Many delegates were happy to have the somewhat confused membership picture in the American Medical Association cleared up, as far as delinquents are concerned. They approved the following resolution as a substitution for a resolution introduced by Dr. George Earl of the Minnesota delegation last June. The latter had proposed that delinquent AMA dues be cancelled for members of any constituent state association which should subsequently make AMA membership compulsory for all its members. The substitute resolution adopted at St. Louis reads as follows:

> Resolved, That any active member of the American Medical Association who failed to pay dues for the year 1950, and who was suspended for such delinquency, may be reinstated during the first six months of 1954 by the payment of 1954 dues, only. Should such an individual fail to pay his 1954 dues by July 1, 1954, he shall continue to be considered delinquent.

A study in membership classifications is now under way by the Board of Trustees, it was announced, which should help to eliminate future membership difficulties.

The proposal to extend medical and hospital insurance protection came in the form of a resolution requesting the Council on Medical Service to be ready with definite suggestions for implementing extensions at the 1954 clinical meeting. The resolution called attention to two important groups of citizens who are largely unprotected at the present time. For these, improved coverage could and should be provided. They are "(a) those individuals who suffer catastrophic or long-continued and highly expensive illness and whose financial resources are not adequate to meet the cost thereof; and (b) those citizens who have retired and are living on small incomes and who are not eligible under presently existing public or private plans."

It was pointed out that the need for such extensions is genuine and also that it represents a soft spot in current plans for insurance protection through which federal subsidies may find a ready entrance.

The delegates also added special emphasis at this session to a standing AMA policy involving all prepaid insurance contracts. The resolution was adopted as an emergency measure, and it specifically condemned all insurance contracts which classify any type of medical service as "hospital service." Pathology, radiology, anesthesiology and physiatry were cited as involved in infractions and violations of this established policy.

In that connection, it should also be noted that recommendations were adopted for careful studies to be made by the Council on Medical Service of all types of union labor medical plans, recognizing both the need for many such plans and the dangers involved in unwarranted extensions of original arrangements and especially emphasizing the fact that medical ethics apply to them with the same force as to any insurance contract.

Ethics Uppermost

Medical ethics came in for discussion and action in many phases and applications. Uppermost in the minds of many delegates were the public charges of unethical practices made against medical men in many popular magazines recently. Their concern and the concern of officers and trustees of the Association was reflected in several resolutions. One of these called upon the Board of Trustees to make a study of the actual extent and seriousness of the unethical conduct alleged in these articles. Another was embodied in an amendment of Chapter IV of the Constitution which was adopted at this meeting pursuant to a request made at the June session. It provides that the Judicial Council may censure or expel service, affiliate and honorary, as well as active members of the association, after due notice, for violations of the principles of medical ethics.

It may be of interest to note here that the resolution introduced by Indiana last June on the subject of federal policies governing the grants-in-aid program for care of crippled children in Indiana has been transmitted to the Department of Health, Education and Welfare where assurances have been given that it will receive prompt and careful attention. The special interest of this resolution, which involves the question of possible charges for those able to pay fees and which applies chiefly to states which do not follow the general grants-in-aid pattern, lies in the fact that it is the one that was hastily and mistakenly siezed upon by *Life* magazine last summer for its ill-natured editorial entitled "Watch It Doc!"

Special emphasis was placed on the principle that physicians may not ethically sell their services or accept a salary for them if they may be exploited in so doing. Decision as to the propriety of any given salary arrangement must depend, however, upon individual facts and circumstances of the case. In response to many inquiries, the Judicial Council re-emphasized the accepted principle that it is unethical for a physician to have a financial interest in a pharmacy in the area in which he conducts his professional activities and where he profits directly or indirectly from the sale of devices or remedies prescribed for his patients. The principle also applies in the case of rental of space to a pharmacy by a physician if the rental is for a percentage on a sliding scale of income.

Actual revision of the Principles of Medical Ethics is under way by the Judicial Council and the Council on Constitution and By-Laws, of which Dr. Louis A. Buie of Rochester is chairman, but waits upon results of studies and questionnaires now being circulated to the membership. Included in changes now under consideration is the proposal made at the June meeting for a change in recommendations for billing procedures where more than one physician participates in the care of the patient. Certain other preparatory steps have been completed and were approved, also, including a change in format and a change in the title which formerly read "Education Information Not Advertising" to read "The Relationship of the Physician to the Media of Public Information."

Bills Approved

Among bills due to come before Congress in 1954 were several which received official sanction of the delegates at this session. One was the Jenkins-Keogh bill which opposes compulsory social security coverage for self-employed persons. The delegates favored, instead, income tax deductions as proposed in the bill, which will permit such persons to build up their own coverage. Another favors transfer of functions, responsibilities and duties of the Department of the Interior and the Bureau of Indian Affairs as they relate to health to the United States Public Health Service; also authorization of admission to United States Public Health hospitals of persons committed by state courts who are Service beneficiaries or narcotic addicts. Still another strongly favored deduction without limitation of medical and dental expenses for income tax purposes. Finally, the delegates reaffirmed their support of the Bricker Resolution (Senate J. Res. 1), limiting treaty-making powers of the President.

Among resolutions presented for the first time at this meeting were several of general interest and importance. One of them called upon the Board of Trustees to make a detailed study of educational standards and requirements of osteopathic, chiropractic and naturopathic schools. This one was adopted and referred to the Board.

Another asked each constituent state association to create its own Committee on Rural Health. A resolution was also adopted asking that all state and territorial medical bodies get in touch with the President's Commission on Intergovernmental Relations which will soon examine the entire grants-in-aid program and offer assistance.

Three resolutions from groups of orthopedists asking that the word "Rehabilitation" be dropped from the title of the Council on Physical Medicine and Rehabilitation were referred to the Board of Trustees for study and a report in June, 1954. The contention of the orthopedists is that rehabilitation is an essential part of their professional function while the function of the Council is largely the investigation of appliances.

Three resolutions, all from Rhode Island, asking that the current "matching plan for interns" in which the Council on Medical Education and Hospitals now participates, be abandoned and that steps be taken to insure a more equitable distribution of interns to smaller hospitals, were not adopted. Extensive committee hearings did not disclose any evidence that the matching plan was depriving small hospitals of interns, and a committee has already been set up, the delegates were informed, to study the whole problem of intern procurement.

In that connection, it should be noted that a resolution asking that the current practice of listing acceptable hospitals, which subscribe to the matching plan, separately from the acceptable hospitals which do not subscribe to the plan, was not adopted either. Instead, the reference committee suggested that the Council prepare one additional list in which non-subscribers are integrated with subscribers. Still another resolution asking that teaching care in veterans' hospitals be given only to veterans with service-connected disabilities failed of adoption, as did a resolution asking that oral prescriptions be permitted for codeine preparations which have little or no habit-forming effect. The latter was refused because of the possibility that usable narcotics might be extracted from large amounts of these preparations.

Malpractice Study Requested

The Board of Trustees was instructed to make a special study of the malpractice insurance situation all over the country, looking to eventual adoption of measures to make certain that this essential type of protection will continue to be available.

Income of the American Medical Education Foundation now totals $1,000,174.00, the delegates were told. This total represents all contributions since the Foundation was started in 1950. Total contributions are now 200 per cent of the total of 1952 and contributions to it from doctors, alone, are 50 per cent greater than in 1952. In addition, the doctors gave $782,885 direct to sixty-five of the seventy-nine medical schools of the United States (the remaining fourteen failed to make a report).

This last amount was given by 22,273 individual contributors. Among other individual contributions mentioned to the delegates was a gift of $2,000 from the American College of Radiology; also the $10,000 a year contributed for the last three years by the Woman's Auxiliary to the American Medical Association. An additional $22,630 has been contributed by state auxiliaries.

Dr. Louis H. Bauer, immediate past president of the American Medical Association, has succeeded the late Dr. Elmer L. Henderson to the post of director of the Foundation. Dr. Edward L. Turner, secretary of the Council on Medical Education and Hospitals, has been designated secretary-treasurer in place of Dr. Donald G. Anderson who resigned recently to become dean of the University of Rochester School of Medivine. Dr. Anderson will continue on the board of directors.

Report from WMA

Drs. Gunnar Gundersen of Wisconsin and Edwin S. Hamilton of Illinois, both trustees of the American Medical Association, were the American delegates to the World Medical Association meeting at the Hague, September 1 to 6, 1953. They reported that an attempt on the part of various government and judicial agencies to draft an international code of medical law had met with vigorous opposition from the doctors' session. The WMA declared officially that only medical men are qualified to adopt a code for medicine; that such a code must be based upon medical ethics and that the WMA, itself, has already adopted its own international code of medical ethics which, incidentally, has been approved by the House of Delegates of the American Medical Association. A chapter on the doctor's duty to society is now being prepared for addition to that code. WMA served notice that it will never accept a code drawn up by jurists or government agencies. The American Medical Association must continue to support the world organization, the delegates were told, because it is the only international body which can speak for the practicing physicians of the world. Dr. Bauer was re-elected secretary-general of the association, with Dr. Austin Smith of Chicago taking the place of Dr. Henderson on the Council, and Dr. Gundersen replacing the late Dr. R. L. Sensenich. The editorial board of the association's *Bulletin* includes Doctors Paul Cibrie, secretary of the French Medical Association; Hugh Clegg, editor of the British Medical Journal; Lorenzo Garcia-Tarnel, secretary of the Spanish Medical Association, and Dr. Smith, who acts as executive editor of the publication. It is of interest to note that the first World Conference on Medical Education met in London in advance of this meeting. Dr. Victor Anderson, of Rochester, is vice president of this conference and attended the meeting.

The report of the general manager, Dr. George Lull, showed a membership of 117,063 in the Association, representing an increase of 7,323 over 1952, according to the reference committee on officer reports, and showing the continued confidence of the profession in the American Medical Association. All nine professional publications of the Association show an increase in circulation, including the *Journal of the American Medical Association,* which currently circulates 167,000 copies weekly. *Today's Health,* on the other hand, circulates 260,000 monthly, of which only 26,000 go to doctor-subscribers, and it shows a deficit of $150,000 for last year. There is a serious question whether publication of *Today's Health* can be continued but it was noted, also, that if doctor-subscribers could be increased to 100,000, the deficit could be erased.

The delegates heard from the new president, Dr. Edward J. McCormick, and from Mrs. Leo J. Schaefer, president of the Woman's Auxiliary to the American Medical Association. Dr. Chester S. Keefer, newly appointed secretary for health in the Department of Health, Education and Welfare, was there, also, to make his first appearance before the delegates, and Dr. Leslie M. Fitzgerald, president of the American Dental Association, was among a group of distinguished guests who brought greetings from other organizations.

The address of the president stressed some very real social and economic problems of the profession.

Public Relations Discussed

The public relations of medicine in America today are not good, Dr. McCormick said, and expensive public relations programs are not going to do much to improve them. State and county medical organizations are the ones that will have to do the work, he declared, and he urged every delegate to go home and campaign for strong grievance committees and the prompt expulsion of all who disregard the principles of medical ethics.

> "This is a grass-roots problem," Dr. McCormick said. "Good public relations cannot be bought. They must be earned by exemplary conduct and genuine service in the public interest.
>
> "We have a policing job to do. Our excellent work in all branches of medicine and the public service are easily forgotten. But not unethical practices of any kind. What we can do is to seek perfection always. In so doing we shall find good public relations. There is no other answer."

Dr. McCormick warned the delegates, also, that the greatest battle to preserve our American system of medicine is yet to come. Already this battle is shaping up in demands for medical care of veterans; in new demands for medical care plans by union labor; in the current system of drafting doctors to care for dependents of service men; in the growing demands for federal subsidies to pay for voluntary insurance. He sees it in statements of elected officials who still believe it is good politics to encourage federal handouts of all kinds and who "by inuendo and by word, magnify the medical needs of the people and pay little heed to the many more important problems affecting American men and women."

Since American medicine is actually the best in the world, Dr. McCormick suggested to popular writers and orators that they devote more of their attention to the far greater problems affecting the health and welfare of the people, such as housing, sanitation, juvenile delinquency. nutrition, un-Americanism in many institutions, dishonesty among public officials, gambling, gangsterism and other cancers on our national life "including the collectivists, socialists, communists and those who, having lost sight of God, have forgotten that we are a great nation because the Constitution was written by men of deep faith in the Supreme Being, faith in opportunity, faith in private enterprise."

Dr. Keefer declared that the major question before the profession is this:

> "How can we continue to produce and promote the finest medical care in the world today?
>
> "Our needs," he said, "are for improved medical education; for co-ordination and extension of facilities and personnel; for geographical extension of services and for bringing the cost within the reach of more people.
>
> "These needs will be met in our free society by the combined effort of the laymen, and of members of the medical and health professions working closely together with a sympathetic understanding in their local communities.
>
> "We need experimentation," Dr. Keefer declared further, "in order to find the answers to many of our problems. Experimentation should be carried out by the profession with the full co-operation of the people of the community and the maximum decision should be made at the community level."

Meetings Well Attended

The Council on Scientific Assembly reported plans well developed for the next annual session in San Francisco, June 21 to 25, 1954, and the next clinical meeting scheduled for December in Miami. It was noted that the winter meetings have been well attended, and the importance of these, as well as the annual meetings, has prompted a consolidation and reorganization of the council activities. A plan was approved for transferring the council from its status as a committee of the House of Delegates to a committee of the Board of Trustees with a permanent office at Association headquarters in Chicago. The council was enlarged and the Bureau of Exhibits was incorporated into its structure.

One of the important events of the winter meeting is the selection of the recipients for the annual General Practitioner of the Year award by the Board of Trustees. The choice this year was Dr. Joseph I. Greenwell, an eighty-year-old active practitioner from New Haven, Kentucky, who has practiced for the last fifty-three years within a 25-mile radius of New Haven. Dr. Greenwell has delivered almost 4,300 babies and, of these, 80 were born last year. He has served as a councilor from the fourth district of the Kentucky State Medical Association for thirty years and is a past president of the Nelson County Medical Society. He is also acting health officer for Nelson County and consulting physician for the Louisville and Nashville Railroad and Gethsemane Abbey. Of his twelve children, eight are living. Two were lost in World War II.

Several Minnesota physicians played an important part in the St. Louis session. Among them were Drs. William L. Benedict, of Rochester, who is also chairman of the Section on Ophthalmology, Dr. Frank J. Elias, of Duluth, and Dr. O. J. Campbell, of Minneapolis, all of whom served on reference committees.

MATERNAL MORTALITY SURVEYS

(Continued from Page 144)

sociation in co-operation with the Minnesota Department of Health. Also co-operating in the study were the Department of Obstetrics of the University of Minnesota and the Minnesota Hospital Association. The maternal mortality rate was 2.0 per 1,000 live births and the report concluded that three-fourths of the deaths were preventable. The Committee's report for 1951 shows that the rate has declined to 0.4 per 1,000 live births and that only about one-third of the deaths studied were considered preventable.

Editorial comment on Minnesota's maternal mortality surveys in the January 1953 issue of the *American Journal of Public Health* is of interest. "In only a sixth of all the states is there a concerted and continuing effort to improve maternal mortality experience through investigation, reporting, and consultation. Minnesota has succeeded in reducing maternal deaths from 2 to 0.6 per 1,000 births (1950)—in one decade—and aims to do still better. Does this story suggest anything to the other five-sixths of the states?"

A. B. Rosenfield, M.D., M.P.H.

◆ Reports and Announcements ◆

AMERICAN COLLEGE OF SURGEONS

A four-day Sectional Meeting of the American College of Surgeons featuring clinics and specialty programs will be held at the Hotel Fontenelle in Omaha, Nebraska, March 1-4, 1954. The medical faculties of Creighton University, the University of Nebraska, and seven local hospitals are co-operating in preparations for the meeting.

Eminent scientists and clinicians from many medical centers will participate in the program which will be of unusual and timely interest.

Morning clinics will be held at the teaching hospitals and at the hotel there will be special sessions in general surgery, ophthalmology, obstetrics and gynecology, otolaryngology, orthopedic surgery, pediatric surgery, thoracic surgery, and urology.

All members of the medical profession are invited to attend. Fellows of the College, members of the Junior Candidate Group, interns and residents are admitted without registration fees. Other doctors are charged a $5.00 fee, all of which goes toward paying a portion of the expenses incurred by visiting speakers.

SYMPOSIUM ON RECENT ADVANCES IN THE STUDY OF VENEREAL DISEASES

The Sixth Annual Symposium on Recent Advances in the Study of Venereal Diseases will be held in the auditorium of the Department of Health, Education, and Welfare, Washington, D. C., April 29 and 30, 1954, according to Dr. James K. Shafer, Chief of the Public Health Service's Division of Venereal Disease.

The sessions are open to all physicians and workers in allied professions who are interested in participating These symposia usually draw hundreds from all parts of the country and are the occasion for exchange of the latest available information by some of the outstanding authorities in the field of venereal disease. Topics discussed at this symposium will cover many aspects of venereal disease control including basic and clinical research, serology, epidemiology, treatment, program operation, and professional education.

AMERICAN HEARING SOCIETY'S ANNUAL COMPETITION KENFIELD MEMORIAL AWARD

Competition for the Kenfield Memorial Scholarship, awarded annually by the American Hearing Society to a prospective teacher of lip reading, will open March 1. Application blanks may be obtained by writing to the society's national headquarters, 817 14th St. N.W., Washington 5, D. C.

Deadline for returning completed applications is May 1. They are to be mailed to Mrs. Eleanor C. Ronnei, care of the New York League for the Hard of Hearing, 480 Lexington Ave., New York 17, N. Y. Mrs. Ronnei is chairman of the American Hearing Society's Teachers Committee. The winner will be announced during National Hearing Week, May 2 to 8.

Funds for the scholarship were subscribed in 1937 in memory of Miss Coralie N. Kenfield, San Francisco, California, who was nationally known for her advanced methods in teaching lip reading.

Winner of the annual award is entitled to take a teacher training course in lipreading from any school or university in the United States acceptable to the Teachers Committee. The scholarship is to be used within one year from the date of award.

A satisfactory applicant for the award must be a well-adjusted individual with a pleasing personality, legible lips, good speech and voice, and no unpleasant mannerisms. Graduation from college with a major in education, psychology and/or speech is a requirement.

Specifications for a hard of hearing contestant include thirty clock hours of private instruction in lipreading from an approved teacher or sixty hours of lipreading in public school classes under an approved teacher. Rules for competition state that an applicant shall plan to teach lipreading with or without other types of speech or hearing therapy.

THE ASSOCIATION FOR RESEARCH IN OPHTHALMOLOGY—MIDWESTERN SECTION

The annual meeting of the Midwestern Section of the Association for Research in Ophthalmology was held Sunday, February 7, 1954 at the University of Chicago Medical Schools, Chicago.

The program for the meeting included the following papers:

Further Contributions to the Enzymology of Corpus Vitreum. *Albert Zeller,* Northwestern University, Chicago.

Metabolic Studies of Lens Epithelium in Vitro. *Bernard Schwartz,* Betty Danes, and *P. J. Leinfelder.* University of Iowa, Iowa City.

The Liebmann Effect in Binocular Perception. *Maressa Hecht Orzack* and *T. F. Schlagel, Jr.,* Indiana University Medical Center, Indianapolis.

Uveitis. A Preliminary Report. *Howard D. Ostler,* University of Iowa, Iowa City.

Studies in Flicker Fusion of the Eye. *Garth J. Thomas,* University of Chicago.

Variations in Quality of Target for Flicker Fusion Fields. *Claude Trapp* and *Paul W. Miles,* Washington University, Saint Louis.

Some Effects of Yttrium 90 Upon the Posterior Ocular Segment. *Frank W. Newell, Paul V. Harper,* and *Anne M. Koistinen,* University of Chicago.

After-Image Transfer Tests in Anomalous Correspondence. *A. K. Hansen,* University of Iowa, Iowa City.

Preliminary Studies in the Aqueous Following Radiation of the Eye. *David Schoch* and *Irving Puntenney,* Northwestern University, Chicago.

Seton Procedure in Glaucoma. *Edward Pushkin, A. C. Biegel* and *Martha Folk,* University of Illinois, Chicago.

The Electroretinogram in Choroideremia. *George W. Bounds, Jr.,* and *Theodore Johnston,* University of Iowa, Iowa City.

Electroretinography in Artificial Partial Avitaminosis A. *Robert J. Davis,* University of Iowa, Iowa City.

FELLOWS ASSOCIATION OF THE MAYO FOUNDATION

Election at the annual business meeting of the Fellows Association of the Mayo Clinic, held at Plummer Hall, Rochester, December 9, resulted as follows: Dr. H. C. Habein, Jr., president; Dr. John O. Godden, vice president, formerly secretary; Dr. S. E. Sivertson, secretary; Dr. Edward B. Waldman, treasurer.

GP ACADEMY ANNOUNCES OUTSTANDING PROGRAM

Attention of general practitioners is called to the Sixth Annual Scientific Assembly of the American Academy of General Practice to be held in Cleveland, Ohio, March 22 to 25, 1954.

A lectureship and exhibit program designed especially to give the general practitioner diagnostic techniques and procedures which apply to everyday practice has been arranged for this unique three-day session.

Speakers, who are top authorities in their fields, include among others, Sir Alexander Fleming of London, discoverer of penicillin; Dr. E. J. McCormick, president of the American Medical Association; Dr. Howard Rusk, outstanding authority on rehabilitation procedures; Doctors George Crile, Jr., and George H. Curtis of the Cleveland Clinic; Dr. Clarence S. Livingood of the Henry Ford Hospital in Detroit; Dr. Sol Katz, associate editor of GP, official publication of the Academy; and Dr. John C. Krantz, Jr., of the University of Baltimore. More than forty-five scientific exhibits will supplement the scientific program which is under the general supervision of Dr. John F. Mosher of Coeymans, New York.

Social events will include a president's reception, music and dancing and a fashion show, coffee hour and book review for visiting women.

BLUE EARTH COUNTY MEDICAL SOCIETY

Election of officers of the Blue Earth County Medical Society was held December 14 at Mankato with the following elected: Dr. R. Wynn Kearney, president; Dr. J. J. Eustermann, vice president; Dr. William S. Chalgren, secretary-treasurer; Dr. L. M. Hammar, delegate to the Minnesota State Medical Association.

FOUR-COUNTY MEDICAL SOCIETY

The Four-County Medical Society and Auxiliary met at the Mayo Foundation House for afternoon and evening sessions, January 6. Talks given in the afternoon were on "Treatment of Hypertension," "Current Use of Antibiotic Drugs," "The Orthopedic Examination of the Back and Hip," with a demonstration, and "The Management of Frequently Encountered Skin Disorders."

After dinner the women toured the new Mayo Clinic building, while the doctors attended a meeting held in conjunction with the regular staff meeting of the Mayo Clinic.

GOODHUE COUNTY MEDICAL SOCIETY

At a dinner meeting held at Red Wing, December 3, the following officers were elected to head the Goodhue County Medical Society: Dr. Ezra Bridge, Mineral Springs Sanatorium, president; Dr. R. V. Sherman, vice president; Dr. George M. B. Hawley, secretary-treasurer.

ST. LOUIS COUNTY MEDICAL SOCIETY

Election of officers of the St. Louis County Medical Society took place at the Kitchi Gammi Club, Duluth, December 11. The following officers were elected: Dr. S. H. Boyer, Jr., installed as 1954 president; Dr. K. R. Fawcett, Duluth, president-elect for 1955; Dr. Walter S. Neff, Virginia, vice president, Virginia; Dr. F. R. Kotchevar, Eveleth, member of the judiciary committee; Dr. Paul Reed, Virginia, member of the economics committee, and Dr. Clarence N. Jacobson, Chisholm, and Dr. Neff, delegates.

STEARNS-BENTON COUNTY MEDICAL SOCIETY

Stearns-Benton Medical Society met at the Granite Bowl, St. Cloud, December 17, electing the following officers: Dr. Henry Reif, St. Cloud, president-elect for 1955; Dr. John Kelly, Cold Spring, president—elected last year; Dr. William Autry, vice president; Dr. E. W. Anderson, secretary.

TRI COUNTY MEDICAL SOCIETY

Doctors and their wives from Kandiyohi, Meeker and Swift Counties met at the annual dinner of the Tri County Medical Society, held in Willmar, December 17. Lakeland Medical Center and Willmar Clinic staffs acted as hosts, with Dr. Roger P. Michels, Willmar, presiding. Musical numbers included one on the violin by Dr. Robert Peterson with Dr. L. J. Opsahl at the piano. Dr. Peterson and Dr. Opshal with Dr. A. M. McCarthy gave a humorous specialty number.

Dr. Paul Giddens, president of Hamline University, spoke on the danger that confronts academic freedoms today, and also pointed out the need for greatly increased facilities in teaching and school rooms for the oncoming tremendous increase in school population.

MINNESOTA STATE BOARD OF HEALTH

Dr. F. W. Behmler, Morris, was re-elected president of the Minnesota State Board of Health at the annual meeting of the board held in Minneapolis, January 12. Prof. Herbert Bosch, University of Minnesota, was named vice president, and Dr. A. A. Chesley was reelected secretary and executive officer. Dr. Behmler has been a member of the State Board of Health since 1940.

Of General Interest

Dr. John W. Ferree, director of community service and education, New York City, and Rome Betts, executive director of the American Heart Association also of New York, were in Minneapolis December 16 to discuss the 1954 Minnesota Heart Fund program set for February. They conferred with **Dr. W. S. Neff,** Virginia, on community service; with **Dr. Karl Anderson,** Minneapolis, on cardiac problems in industry, and **Dr. John Briggs,** Saint Paul, on professional education. They also met with the State Medical Association's executive committee during the day, and in the evening with the general membership at a meeting at the University of Minnesota.

* * *

Yellow Medicine and Renville Counties qualified for tuberculosis accreditation recently. Attended by approximately ninety persons from the two counties, a banquet was given for the occasion December 7, at the Romberg Hotel, Sacred Heart. To qualify for accreditation a county must have a tuberculosis death rate averaging ten or less per 100,000 population for a five-year period. Yellow Medicine County had a 3.7 and Renville a 5.8 rate for the years 1948 to 1952. The county must also have a low infection rate which is established by sampling high school seniors through a tuberculin testing program.

Dr. M. S. Nelson, serving for many years as president of the Yellow Medicine County Tuberculosis Association; **Dr. Lewis S. Jordan** and **Dr. Kathleen Jordan** of the Riverside Sanatorium, Granite Falls, and Clara Thorpe, the organization's secretary for many years, were presented with framed certificates in recognition for the work they have done in combatting tuberculosis. The awards were made by Marguerite Breen, public relations officer for the Minnesota Tuberculosis and Health Association.

* * *

Dr. Pao-shu Chen, Formosa, and Dr. Andreas Angara, the Philippines, visited the Hennepin County League for Planned Parenthood recently for information they might use to help their countrymen. **Dr. Marian Grimes,** planned parenthood clinician, explained the operations of the clinic, and gave the two doctors data on birth control. Dr. Chen, public health student at the University of Minnesota on a World Health Organization scholarship, said there was a great need of birth control in Formosa, where, though the area is the same size as Maryland and Delaware combined, has a population four times that of the two states. Dr. Angara, studying public health at the University of Minnesota on a year's scholarship from the Foreign Operations Administration, was primarily interested in the "rhythm" method of planned parenthood for the underpopulated Philippines. Both doctors said the greatest problems in health, in their respective countries, were sanitation—water supply and waste disposal.

Dr. John Grant, Sauk Centre surgeon, specializes in "organs" in his spare time. He builds pipe organs, which he says he learned how to build when he read a few books and talked to some "guys in the business" during his medical school days. After the reading and advice from "the guys in the business," he began buying parts and assembling the pipe organs. His last venture is a 1,300-pipe organ at the Church of the Good Samaritan at Sauk Centre which he built with the help of the pastor, Rev. Nor Schoenheider. The organ, built from parts secured from churches in Minneapolis, St. Paul, Excelsior and Willmar, was dedicated December 20.

* * *

Among Fellows of the Mayo Foundation receiving degrees at the Commencement exercises at the University of Minnesota December 10 were the following: **Dr. Robert C. Bahn,** Ph.D. in pathology; **Dr. Homer R. Warner,** Ph.D. in physiology; **Dr. Dean P. Epperson,** Ph.D. in surgery; **Drs. Earl F. Beard, Fred Z. Havens, Jr., Alexander M. Minno, Waldemar N. Person, John D. Ruff** and **Robert G. Tompkins,** M.S. in medicine; **Dr. Gilbert A. Reese,** M.S. in ophthalmology; **Dr. Eran O. Burgert, Jr.,** M.S. in pediatrics; **Dr. Milton E. Kurth,** M.S. in plastic surgery; **Dr. Charles F. Smith,** M.S. in radiology; and **Drs. Mitchell S. Madison, J. D. Mortenson, Harold W. Neuman** and **Donald N. Vivian,** M.S. in surgery.

* * *

Dr. Gordon Uhley, Crookston, is taking a year's leave of absence from the Northwestern Clinic, Crookston, in order to do graduate work in urology with Dr. S. D. Creevy at the University of Minnesota, Dr. Uhley's alma mater.

* * *

Dr. Marie Bepko, Cloquet, has apparently mastered the art of budgeting time. She is physician, partner with her husband, **Dr. R. H. Puumala,** homemaker, and active in several professional and civic organizations.

Born in Chicago of Czechoslovakian parents, Dr. Bepko graduated from the University of Illinois, College of Medicine, and interned at the American Hospital during which time she married Dr. Puumala, who was at this time resident at University of Illinois Research Hospital. After their first child was born Dr. Bepko continued her preparation by taking a six months' residence in psychiatry at the state hospital in Elgin, Ill. The family moved to Cloquet in 1935 where the two doctors have since practiced.

Though both doctors have travelled extensively, they have not taken their vacations together until last summer, when with their two children, they motored to Anchorage, Alaska, via the Alcan highway. Besides her duties to her family, Dr. Bepko is vice president of the Pan American Women's Alliance; life member of the American Medical Women's Association; president of the Minnesota State Medical Women's Association; active in community activities which include Parent-Teacher work, projects of the Business and Professional Women's Club, and other organizations.

* * *

Dr. J. W. Bratholdt and **Dr. L. J. Larson,** Watertown, moved their offices into the newly constructed Bratholdt Clinic December 12. The clinic is located across the street from the Bratholdt Hospital.

* * *

Dr. Harold M. Solvason, formerly located at Hennepin and Franklin Avenues, Minneapolis, has opened a new office at Fifty-fourth and Nicollet, Minneapolis. Dr. Solvason is a graduate of the University of Minnesota School of Medicine.

* * *

Dr. Francis J. Braceland, Hartford, Connecticut, formerly of the Mayo Clinic, is a member of one of the divisions of the task force on Federal Medical Services of the Hoover Commission. The activities of the division is to gather information from government agencies and other sources before any conclusions are reached or any recommendations given to the Commission.

* * *

Dr. Edward Zupanc, formerly of Granville, Wisconsin, who has served with the Armed Forces for two years in Japan, will open an office in Duluth, specializing in pediatrics.

* * *

Dr. Swan Ericson, Le Sueur, has retired after practicing medicine in the community for the past thirty-one years. Dr. Donald A. Limbeck. graduate of the University of Nebraska, Medical School, is taking over Dr. Swanson's practice.

* * *

Dr. Edward Q. Ertel, Ellendale, recently contributed a microscope to the Ellendale High School. The gift included a wood carrying case, glass bell protective cover, and immersion lens.

* * *

Awarded for his work in establishing radiological teaching programs in various medical schools in India, **Dr. Leo G. Rigler,** Minneapolis, received the gold medal of the Radiology Society of North America December 23. Dr. Rigler, head of the University of Minnesota's Radiology Department visited India early last year as a member of the World Health Organization specialists' team.

* * *

Dr. William Feigal, Falls Clinic, Thief River Falls, addressed the monthly meeting of the Roseau County Medical Society, December 11. Together with his subject, "Urology in Northern Minnesota," he also reviewed x-rays, showing pathological findings in this area with their treatment and clinical course.

* * *

Dr. David R. Johnson and **Dr. Lyle A. French,** Minneapolis, spoke on the topic, "Cerebral Hemispherectomy for Intractable Seizures," at the regular meeting of the Minnesota Society of Neurology and Psychiatry, at the Town and Country Club, St. Paul, January 12. **Dr. Frank Kiesler,** also Minneapolis, spoke on "The Patient who Can't be Cured."

* * *

Dr. D. H. Garlock, Bemidji, has recently been certified as a Tree Farmer in the state and national tree farm program. His 155-acre farm east of Lake Bemidji was approved by the tree farm committee of Keep Minnesota Green.

* * *

Dr. F. H. Magney, Duluth, was given the Silver Beaver Award. high scouting honor, at the annual business meeting of the North Star Council, Boy Scouts of America, at Duluth Chamber of Commerce quarters December 7. Dr. Magey was cited for long service (since 1935) in keeping the boys fit "in matters pertaining to health."

* * *

Dr. Donald H. Honath, Detroit, Michigan, has joined **Dr. A. J. Olson** and **Dr. F. C. Anderson,** at their clinic in Owatonna. Dr. Honath is a graduate of Wayne University College of Medicine; interned at Evangelical Hospital, Chicago, and finished a four and a half-year residency in general surgery at Mt. Carmel Mercy Hospital, Detroit.

* * *

A new series of industrial safety schools sponsored by the Duluth Chamber of Commerce was held in Duluth, December 9. **Dr. John F. Briggs,** Saint Paul addressed the general session on "Optimism in Heart Disease." **Dr. James Tetlie,** Duluth, spoke on eye injuries; **Dr. Kenneth A. Storsteen,** Duluth, on gastro-intestinal disease; **Dr. Robert J. Goldish,** Duluth, on diabetes; **Dr. John Schmid,** Duluth, on industrial dermatitis; **Dr. Walter Kelley,** on burns; **Dr. William Grohs,** hernias; **Dr. Elizabeth Bagley,** "the home, an important industry," at the women's section.

* * *

Dr. R. J. Ripple, Saint Paul, spoke to members of the Washington County Medical Society at the meeting, December 8, at Stillwater, on the problems of resuscitation and anesthesia. Doctors from Forest Lake and Hastings attended the meeting which was followed by dinner.

* * *

Dr. G. M. Hawley spoke on "Ministering to Hospital Patients" at a meeting of the Red Wing Ministerial Association held December 7, at the Baptist parsonage, Red Wing.

* * *

The new Veterans Research Hospital, Chicago—key hospital in the veterans hospital system—has three Minnesota doctors on its staff. **Dr. Richard V. Ebert,** chief of medicine; **Dr. Ben I. Heller,** chief of the metabolic section; **Dr. Craig Borden,** chief of the cardio-vascular section. All three men have faculty appointments at Northwestern University.

* * *

Dr. F. H. Baumgartner, Albany, has resigned from his office as mayor of Albany. For ten years he has spearheaded drives that have brought about improvements in the village, but his responsibilities as physician has increased to such an extent, he was unable to carry on both tasks.

On January 2, **Dr. K. A. March,** Cambridge, was joined in his practice by Dr. Michael Danyluk, originally from Germany. Dr. Danyluk has been on the staff at the Swedish Hospital, Minneapolis, since coming to Minneapolis in 1950. He studied medicine at the University of Munich, Germany.

* * *

Dr. Albert V. Stoesser, Professor of Pediatrics and Allergy at the University of Minnesota, spoke on "Allergy and Your Child's Behavior" at a meeting of the Child Psychology Study Circle, January 4, at the Groveland Park School Auditorium, St. Paul.

* * *

The complete list of new members from Minnesota accepted by the American College of Surgeons for 1953 is as follows:

Grant L. Griebie, Brownton, surgery; Hubert D. Clapp, Crookston, obstetrics-gynecology; Philip F. Eckman, Duluth, surgery; Francis L. Stutzman, Montevideo. surgery; Clarence W. Wasmund, Red Wing, ophthalmology; John W. Kirklin, surgery, Karl A. Lofgren, surgery, and Frank Charles Mann, pathology, all of Rochester; Hanns C. Schwyzer, Saint Paul, surgery, and Jack R. Pierce, Virginia, obstetrics-gynecology; Ivan D. Baronofsky, surgery; Walter P. Eder, surgery; Milton Feinberg, surgery; Davitt A. Felder, surgery; Geddes B. Flagg, ophthalmology; William Harold Ford, surgery; George L. Garske, urology; John K. Grotting, plastic surgery; Carter W. Howell. surgery; Arthur W. Ide, Jr., surgery; C. Walton Lillehei, surgery; and Henry A. Norum, surgery, all of Minneapolis.

* * *

Dr. Ernest O. Hanson, who has been practicing in Carlton, has opened his office in Cloquet recently.

* * *

The Hayfield Medical Center, a $10,000 community project, was ready for occupancy January 15, by **Dr. Harold J. Elliot,** former missionary doctor in Africa, who came to Hayfield last fall.

* * *

Dr. J. E. Ponterio, Shakopee, recently had $140 stolen from his cash box which was kept in his office desk. Filing cabinets and desk drawers had been rifled.

* * *

Dr. Henry G. Moehring, radiologist of the Duluth Clinic, Duluth, is one of the co-authors of a three-volume book entitled "Clinical Roentgenology," published by Charles C Thomas, Springfield, Illinois. The first volume is now being offered for sale.

* * *

Progress is being made on the new Adams Clinic, Chisholm, which will be ready for use sometime in February. **Dr. Clarence Jacobson, Dr. Bayerd French,** and **Dr. George Erickson** will have their offices in the building plus rooms and facilities for x-ray and laboratory work.

* * *

More than 1,050 doctors attended the twelfth annual meeting of the American Academy of Dermatology and Syphilology at the Palmer House, Chicago, recently. Among officers elected was **Dr. John F. Madden,** Saint Paul, elected vice president.

Dr. Solveig Gislason, New Ulm, recently accepted a position on the medical staff at the State Hospital, St. Peter. Dr. Gislason, born in a log cabin near Gardae, North Dakota, attended North Dakota schools—Normal School, Valley City, and University of North Dakota, Grand Forks, and then took a claim in Montana. She lived alone on the ranch riding horseback to the school where she was teaching. Interest in further education sent her to University of Minnesota where she graduated from the Medical School in 1921.

Dr. Gislason has written children's books that have been recognized and displayed at fairs and seminars by educational authorities in foreign countries such as Belgium, India, et cetera. She has operated an antique shop in New Ulm, and has also been active in civic and social affairs, especially as president of the New Uum Recreation Commission.

* * *

Appreciated by the communities he served so long, **Dr. Mose Lane Strathern,** Gilbert, still makes his rounds though he began his practice on the range in 1911. He moved to Coleraine with his bride that year to take up practice at $100 a month; later he moved to Gilbert, which was then one of the boomingest towns on the Range. During the horse and buggy days, the fee for delivering babies was $5, when the fee went up to $15, Dr. Strathern bought an automobile. Last October 22, he with nine other members of the team that played Michigan a six to six game in 1904, had a reunion in Minneapolis. Dr. Strathern was captain of the Minnesota team that year.

* * *

Dr. Alan Challman, of Minneapolis, attended the annual meeting of the Advisory Committee to the Psychiatry and Neurology Division of the United States Veterans Administration held in Washington, D. C., January 18 and 19, 1954.

* * *

From a reader: In a recent issue (November) of your excellent magazine, you announced in your news column, the *three* young physicians named by *Time* magazine as "Newsmakers of Tomorrow!"

You neglected to name **Edmund B. Flink, M.D.,** director of Internal Medicine at Veterans Hospital, and member of the University of Minnesota Medical staff. His recognition was as deserving as the other gentlemen. (*We regret the omission.*—The Editors.)

* * *

Dr. George D. Haggard, Minneapolis, observed his ninety-seventh birthday January 18. At this time he also received a Life Membership Certificate from the Minnesota Medical Association of which he is justly proud. He has been interested in the Hennepin County Medical Society over the years, and to use his own words, he said, "Why I can recall years ago when I was secretary of the county society, we were gratified that we could boast of eighty members—and now the county society has well over 1,000 members."

Dr. Haggard retired completely from his practice only two or three years ago. He is making his home now with his daughter.

HOSPITAL NEWS

The St. Cloud Hospital has named the following medical staff for the coming year: **Dr. Otto Phares**, president; **Dr. E. M. Anderson**, president-elect; **Dr. J. B. Gaida**, vice president; **Dr. Vernon Neils**, secretary. Serving on the executive committee with the new officers are: **Dr. L. M. Evans, Dr. L. A. Veranth** and **Dr. Karl Walfred**, past president. Chiefs of services include: **Dr. H. E. Sisk**, medicine; **Dr. C. F. Brigham, Jr.**, surgery; **Dr. R. N. Jones**, anesthesia; **Dr. F. J. Schatz**, obstetrics; **Dr. C. S. Donaldson**, orthopedics; **Dr. W. T. Wenner**, EENT; **Dr. H. J. Reif**, pediatrics; **Dr. P. E. Stangl**, clinical and pathological laboratories; and **Dr. C. B. Nessa**, chief of radiology.

* * *

The Duluth, Missaba and Iron Range Railway made a contribution of $300,000 toward construction of a new hospital at Two Harbors. The money is to be used by the North Shore Memorial Hospital, Incorporated, which is a non-profit group, organized under Minnesota laws, and backed by the Two Harbors Independent Citizens Committee. **Dr. Allen Gunn-Smith**, spokesman for the hospital indicated the group planned the construction of a fifty-bed hospital that would serve the entire North Shore area.

* * *

Fairmont Community Hospital has the following new officers on the medical staff: **Dr. E. E. Zemke**, president; **Dr. O. E. Wandke**, vice president, and **Dr. Neil Wickerson**, secretary-treasurer.

* * *

The annual meeting of the medical staff of St. John's Hospital, Saint Paul, named **Dr. T. S. McClanahan**, chief of staff, December 15; **Dr. Robert W. Emmons** was named first vice chief; **Dr. P. G. Polski**, second vice chief; **Dr. Jack W. Strand**, secretary-treasurer; **Dr. C. Kenneth Cook**, retiring chief of staff, was named to the executive committee for a three-year term along with **Dr. H. L. Stolpestad.**

* * *

The need for a community hospital in Forest Lake is great, according to a recent editorial in *Forest Lake Times.* The need is also great for public spirited people living in the community to attempt the project, while the need for federal aid is also great. The area designated four years ago as one of the high-priority areas for a thirty-five-bed general hospital. **Dr. Helen L. Knudson**, State Department of Health, indicates that she has been unsuccessful finding people interested in the hospital program.

* * *

Tentative plans for the Douglas County Hospital, Alexandria, were shown by Architect Frank Jackson at a meeting of the Advisory Committee recently. Plans, that call for a new hospital architecture, consists of diagonal wings extending Y-like arms from each corner of the one-story building. The hospital, capacity forty-eight beds, will be located on a 17-acre plot of ground in the southeast section of the city. **Dr. L. F. Wasson**, Alexandria, and **Dr. E. E. Emerson**, Osakis, are among the committee members.

Plans for a fund-raising project to finance building a community hospital at Cloquet was approved at a joint meeting of the Cloquet Civic Affairs Council and the rural-urban committee of the Cloquet Chamber of Commerce recently. A poll was taken by postcard which indicated that 97.3 per cent of the people in the community were in favor of the project.

* * *

New officers of the medical staff of Glenwood Hills Hospital were elected at the annual meeting held December 16, 1953, as follows: **Dr. J. A. Resch**, president; **Dr. John Schumacher**, vice president, and **Dr. Irving Bernstein**, secretary.

* * *

MINNESOTA BLUE CROSS-BLUE SHIELD

At its meeting on December 30, 1953, the Board of Directors of Blue Shield accepted the resignation of Arthur M. Calvin as Executive Director effective as of January 1, 1954. In view of the fact that the increased duties and responsibilities which Mr. Calvin's recent election to the office of President of Blue Cross have imposed upon him may prove too great for his continued active leadership in the executive management of Blue Shield, the Board of Directors after considerable deliberation accepted Mr. Calvin's resignation. In so doing, the members of the Board highly commended Mr. Calvin for his distinctive contribution to the successful organization and growth of Blue Shield. As Executive Director from the inception of Blue Shield six years ago, he has seen it grow to cover 600,000 Minnesotans, and its payments to doctors for services rendered subscribers now exceed $4,000,000 annually.

The Board of Directors, having accepted Mr. Calvin's resignation, appointed Dr. Edwin J. Simons as Executive Director. Dr. Simons will continue the executive management of Minnesota Blue Shield, which is now one of the twelve largest Blue Shield Plans in the nation. Dr. Simons was formerly engaged in the practice of medicine at Swanville, Minnesota, for a period of twenty-five years. For over three years, he has served as Medical Director of Blue Shield, and in the past year, he has also served as its Associate Executive Director.

Blue Shield and Blue Cross will continue to co-ordinate their activities as they have in the past. Blue Cross will continue to provide Blue Shield with such services as enrollment, billing, accounting and statistical services. The two organizations will remain in close co-operation to promote the development of both plans in order that the people of Minnesota may be provided with the best in medical-hospital service and coverage.

One person out of every six covered by Minnesota Blue Cross used hospital care during 1953, an increase over the care used in 1952.

Approximately 942,000 days of hospital care were provided by Blue Cross, an increase of about 40,000 days over 1952. This increase in hospital utilization also necessitated an increase in Blue Cross funds paid out. Almost fifteen million dollars was paid out for Blue Cross subscribers and their families in 1953 compared with payments of $12,500,000 in 1952.

Minnesota Medicine

THE PRESENT STATUS OF SURGERY FOR AORTIC STENOSIS

ROBERT P. GLOVER, M.D.
Philadelphia, Pennsylvania

THE PROBLEMS associated with the surgical alleviation of aortic stenosis have to date presented far greater difficulties than any of the other stenotic valvular lesions. These problems have been recognized for many years since the first surgical attempt to relieve an obstructed aortic valve was made by Tuffier in 1913.[5] Their exact nature, however, has only been fully appreciated within the past half decade, during the recent renaissance of intracardiac valvular surgery. Although as much if not more time and valiant effort, both experimental and clinical,[2,3,4] has been directed toward this most intractable of valvular lesions as has been devoted to tricuspid, pulmonary and mitral stenosis, equal success has not as yet been forthcoming. There are a number of reasons for this state of affairs.

Anatomically, the valve is the least accessible to exploration, for it lies centrally placed within the confines of the heart. In aortic stenosis, the left ventricular myocardium is greatly hypertrophied, which, together with the tremendous vascular pressure generated within its outflow tract, prevent the use of a subaortic transmyocardial incision for the insertion of finger or instrument similar to that used in pulmonary valvulotomy, because of the ensuing uncontrollable hemorrhage. The valve cannot be effectively reached through an auricular appendage. The position of the ostia of the coronary vessels lying directly behind the valve leaflets makes direct reconstructive surgery hazardous (Fig. 1).

Pathologically, there is an early fusion of the three valve cusps, the margins of which become thickened, rolled, eburnated and infiltrated with calcium very early in the course of the disease. This is due, in part, to the disease itself but more particularly to the location of this valve in the course of the blood stream. The valve lies in a confined space of small diameter and is the recipient of the full head of vascular pressure from the strongest of contracting cardiac chambers—the left ventricle. The factor of vascular *trauma* is, therefore, of great importance for, following initial fibrotic agglutination of the cusp margins, there is a constant and steady deposition of traumatic elements such as fibrin and calcium from which there can be no relief. Thus, calcification develops early and as the leaflets are relatively small in surface area, almost complete immobility and fixation may be rapidly evident. Some flexibility of the cusps at their attachment to the aortic ring may remain for a time but this is less prominent than that seen in the stenotic mitral valve. This factor of *trauma* no doubt partially explains the fact that the anteromedial leaflet of the mitral valve (also called the aortic or septal leaflet) is the seat of the greatest calcification in mitral stenosis, for it lies nearest the aortic ring in the high flow pressure left ventricular outflow tract and also receives the brunt of the vascular ejection at the time of left ventricular contraction (Fig. 2). Therefore, from a pathologic standpoint, surgical intervention in aortic stenosis, to effectively re-

---

Presented in the Symposium on Recent Advances in Cardiovascular Physiology and Surgery, University of Minnesota, Minneapolis, September 16, 1953.

Dr. Glover is Thoracic Surgeon to Episcopal, Presbyterian and Lankenau Hospitals and St. Christopher's Hospital For Children; Clinical Professor of Thoracic Surgery, Hahnemann Medical College and Hospital, Philadelphia, Pennsylvania.

store a measure of normal valve leaflet motion, must be carried out before extremes of the above described process are reached. To wait longer merely compounds the likelihood of surgical failure, for in consequence of the valvular change, the left ventricular myocardium hypertrophies and dilates, in due time to wear out and become incapable of effective action. As the left ventricle is the cornerstone of the heart and circulation its failure predicates irremediable disaster. This is in contrast to the findings in mitral stenosis, where, despite profound pathological and clinical changes even to the point of prolonged congestive failure and invalidism, the left ventricle retains its indispensable function—actual, compensatory and recuperative—almost to the end.

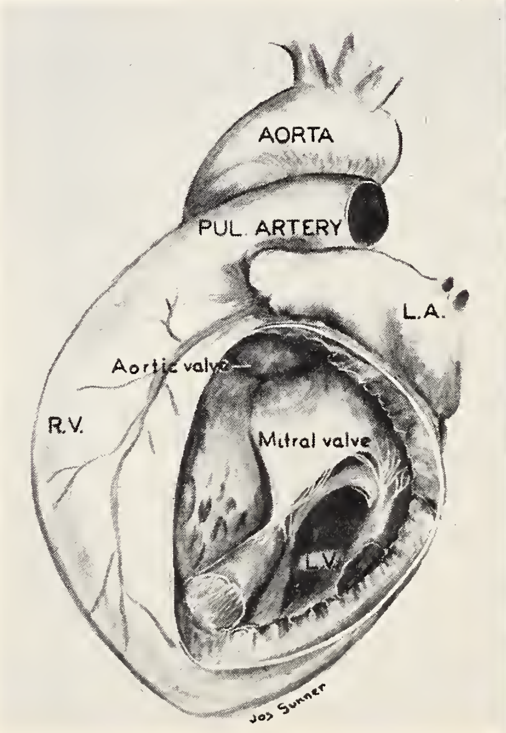

Fig. 1. Note the aortic valve lying beneath the pulmonary artery almost centrally placed within the cardiac mass. Safe access to the valve can be gained through the left ventricular myocardium near its apex.

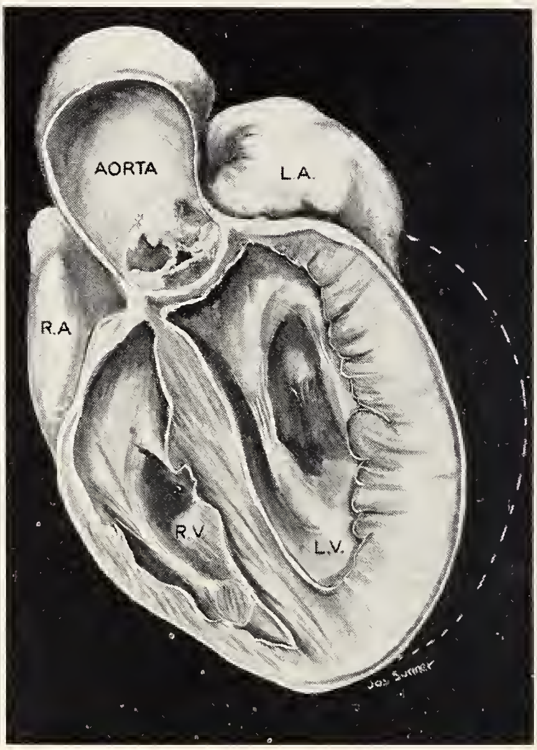

Fig. 2. Early calcification of the aortic valve with progressive concentric hypertrophy of the left ventricular myocardium. Observe the post stenotic dilatation of the ascending aorta.

Physiologically, because of the jet-like ejection of relatively small amounts of blood with each left ventricular contraction, the systolic blood pressure may not reach high levels although it is perhaps sustained and maintained longer than usual. Diastolic pressures, however, are high so that the pulse pressure is small and coronary artery filling, now under greater stress because of the demands of an increased myocardial mass, may be inadequate. As such, these patients are often precarious anesthetic risks, to say nothing of the superimposed danger of surgery.

Surgical Objective

Despite these apparent roadblocks, considerable progress has been made. The experimental work which has been undertaken in an effort to find a satisfactory surgical solution to this problem has been previously reported.[1] Briefly, the present operative approach calls for a left lateral thoracotomy, the introduction of a dilating instrument through a relatively avascular area of the left ventricle near its apex and lateral to the left descending coronary artery. The dilator is directed through the valve by passing it over a previously placed wire guide, the olivary tip of which can be felt in the aorta prior to the insertion of the larger instrument through the myocardium. The dilating head opens in triangular fashion causing the fused commissures of the stenotic valve to separate, partially relieving the stenotic obstruction and restoring a measure of valve action (Fig. 3).

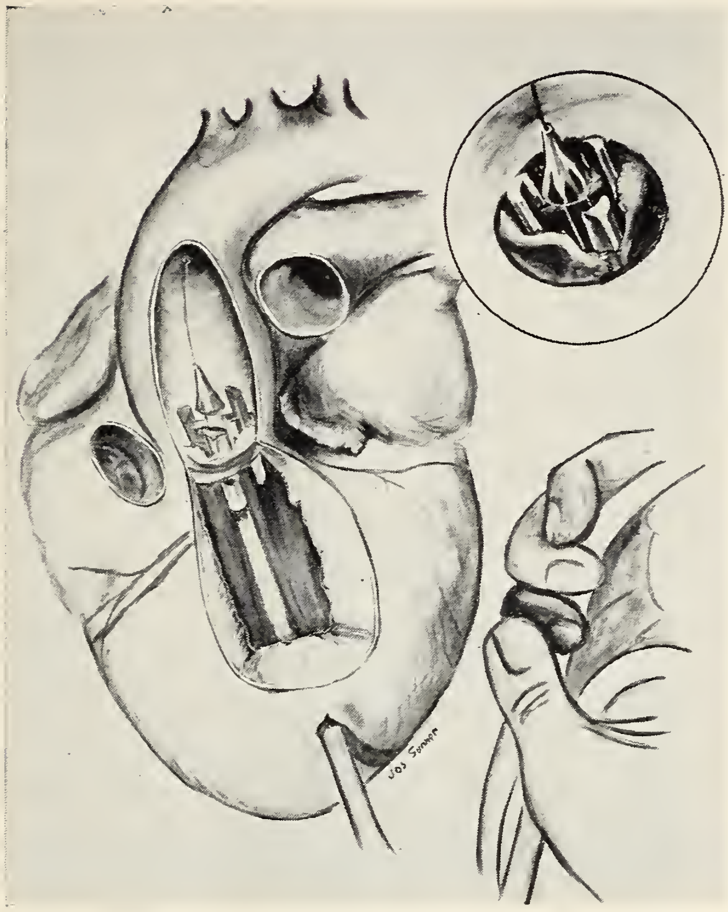

Fig. 3. The aortic dilator inserted through the myocardium of the left ventricle near its apex. This instrument is guided through the aortic valve by threading it over a fine olive-tipped wire previously placed through the valve. The insert depicts the three flanges of the dilating head separating the commissures. The self-rotating head settles automatically into the V-shaped commissures of the fused aortic cusps.

TABLE I.
CLINICAL CLASSIFICATION OF AORTIC STENOSIS

Stage	Symptoms
1	Asymptomatic—murmur only
2	Fatigue, heart consciousness, palpitations, visible pulsations
3	Syncope, Angina—reduced cardiac output
4	Episodic pulmonary congestion
5	Congestive failure

TABLE II. AORTIC STENOSIS

Stage	Results				
	No.	Excellent	Improved	Unimproved	Deaths
1. Asymptomatic—murmur only	0	—	—	—	—
2. Fatigue, heart consciousness, palpitations	2	2	—	—	—
3. Syncope, angina	10	2	6(3*)	1	1
4. Episodic pulmonary congestion	5	—	3	1	1(1*)
5. Congestive failure	5	—	—	—	5(2*)
Totals	22	4	9	2	7

*Combined Mitral and Aortic Commissurotomies.

Clinical Classification (Table I)

The necessity for translating the present rationale of surgery for aortic stenosis into reasonable, practical language has called for the development of a classification for the recognition of clinical states either applicable or unsuitable for surgery at the present time.

The recognizable clinical stages through which the average patient with aortic stenosis will pass are well known, although perhaps not readily defined in the mind of the physician in the light of surgical advances. *Stage 1* is the period during which the typical systolic murmur develops before symptoms result. *Stage 2* marks the onset of an ill-defined period where the patient becomes subjectively aware of his forceful heart action, palpitations develop, easy fatigue becomes noticeable and his attention may be called to the unusual, visible pulsations in his supraclavicular and suprasternal notches. Admittedly, this stage is not specifically characteristic of aortic stenosis *per se,* but when seen with an aortic systolic murmur the combination takes on added significance. *Stage 3* ushers in the obvious period of progressive disability due to a diminishingly effective cardiac output as evidenced cerebrally by spells of dizziness and actual syncope. Myocardially, substernal discomfort, tightness, effort and angina with its characteristic distribution bespeak inadequate coronary flow. With beginning left ventricular failure, *Stage 4* is characterized by episodes of pulmonary congestion and edema at first rather easily controlled by medical measures but shortly to become refractory to even the most vigorous management. *Stage 5* connotes impending disaster and an early demise, for in addition to left ventricular failure, superimposed right heart failure with hepatomegaly, ascites and peripheral edema now labels the heart picture as one of irretrievable damage not to be reversed by any regime—medical or surgical.

Results of Surgery (Table II)

Twenty-two cases have undergone aortic commissurotomy and six of these have been combined with a mitral commissurotomy because of concurrent bivalvular stenosis. One patient (Stage 2) done over three years ago remained completely asymptomatic for two years. During the past twelve months, although working steadily and living a normal life, he has noticed some minor precordial tightness with exercise after meals which had not been present during his first two postoperative years. This patient's aortic commissurotomy was performed with our original dilator which did not have the strength or wide diameter opening of the present more refined instrument which may account for his present status. Clinically, there has been little change in his cardiac findings.

The remaining twenty-one cases have been operated upon in the past eighteen months. The pertinent data can be seen at a glance in Table II. The over-all mortality has been high which may have been influenced somewhat by the inclusion of cases with bivalvular surgery. The observation of paramount importance, however, is that cases done in the early symptomatic phase (twelve cases—Stage 2 and 3) run a risk at present of only 8.3 per cent and even including those in Stage 4, when left ventricular failure with pulmonary edema has entered the picture the mortality rate is a reasonable 11.7 per cent. One has but to consider the seriousness of the disease and the utter hopelessness of its immediate prognosis to appreciate that such results are highly encouraging at this stage of our surgical progress. When true congestive failure has developed (Stage 5) it is doubtful whether much, if any, salvage can be either expected or obtained.

Conclusions

The natural course and progression of rheumatic stenotic valvular disease has dictated the necessity for the mechanical relief of its acquired stricture. Mitral and aortic commissurotomy have become major adjuncts in the over-all and continuing care of victims so afflicted. Provided the patient is referred for surgical intervention early in the course of his symptomatic progression, such a patient can be restored to a high level of efficiency and enjoy a more normal life as a useful and productive citizen. The burden of selecting patients at *an early stage* rests squarely on the shoulders of the practicing physician and this responsibility can no longer be avoided or postponed.

SEPTAL DEFECTS

A ventricular septal defect probably is the commonest congenital cardiac anomaly. *Although a small ventricular septal defect (maladie de Roger) makes the most noise, it is of the least physiological importance.* The murmur is systolic in timing, may be short or long, is loud, harsh and usually maximal along the lower left sternal border; the heart will be normal in size. When the defect is large or high in the septum, the murmur may be loudest over the pulmonic area and the heart may show some enlargement. This latter type is often misdiagnosed as a patent ductus because of the location of the murmur. Surgical repair of ventricular defects is still in the experimental stage.

In an auricular septal defect the systolic murmur is usually maximal over the base of the heart. This condition usually causes more of a physiological strain than a ventricular septal defect resulting in an enlargement of the right side of the heart and fullness of the pulmonary vessels. Surgical repair of auricular defects is being done, but experience is still limited.

A patent foramen ovale should not be confused with a true auricular septal defect. In patency of the foramen ovale, blood cannot flow from the left auricle to the right auricle because of the valve on the left side. Except under abnormal conditions, blood cannot flow from the right to the left because the pressure in the left auricle is higher than in the right auricle. Therefore, a foramen ovale, although anatomically patent, is functionally closed and clinically of no significance.—From "Diagnosis of Congenital Cardiac Defects in General Practice," American Heart Association.

APPLICATION OF A MECHANICAL HEART AND LUNG APPARATUS TO CARDIAC SURGERY

JOHN H. GIBBON, Jr., M.D.
Philadelphia, Pennsylvania

IT IS A PLEASURE to be here and to talk about a subject in which I have been interested for many years. The ultimate objective of my work in this field has been to be able to operate inside the heart under direct vision. From the beginning, I have not only been interested in the substitution of a mechanical device for the heart, but also for the lung. We have always considered congenital abnormalities of the heart the most suitable lesions for operative repair. Many of these abnormalities are septal defects. In the presence of a septal defect, shunting the flow of blood around one side of the heart with a pump, will not provide a bloodless field for operative closure of the defect. An apparatus which embodies a mechanical lung, as well as pumps, enables you to shunt blood around both the heart and lungs, thus allowing operations to be performed under direct vision in a bloodless field within the opened heart. Furthermore, an apparatus which embodies a mechanical lung enables you to provide partial support to either a failing heart or failing lung where a major operative procedure is not contemplated. Such an apparatus can also be used as an adjunct during the course of a major operative procedure. This partial support of the cardiorespiratory functions consists in removing venous blood from some peripheral vein continuously, oxygenating the blood and getting rid of the carbon dioxide in it and then injecting the blood continuously in a central direction in a peripheral artery. Of course, such partial circulation, or cardiorespiratory support, requires the use of a mechanical lung in the circuit.

I shall not describe in detail the entire apparatus. I shall merely discuss six aspects of the problem which I consider of fundamental importance. Four of these concern the apparatus itself, and two concern problems which arise on opening the heart and operating within it under direct vision.

The first feature of a mechanical heart-lung apparatus is a suitable pumping mechanism to move the venous blood from the subject, through the apparatus, and back into an artery of the subject. There is no real problem about a pumping apparatus. There are many ways of moving blood through tubing without producing significant amounts of hemolysis. We have used for many years a roller type of pump which does not contain any internal valves. Such pumps are extremely simple. Because of the absence of valves, the blood circuit is easy to clean and there are no stagnate regions where fibrin might be apt to form. There are many other advantages in this type of pump such as the simple and rapid control of the rate of blood flow. The pumps cause no significant hemolysis. In human patients in which we have used the apparatus, hemolysis has always been well below 100 mg. of free hemoglobin per 100 ml. of plasma. In animal experiments, hemolysis is similarly minimal.

The second main feature of a mechanical heart-lung apparatus is the mechanical lung itself. This presents far more difficulties than pumping blood. I am sure that the most efficient apparatus for performing the functions of the lung has not yet been devised. Our present mechanical lung, however, provides a reasonably satisfactory working solution to this problem. The mechanical lung performs the gas exchange required for respiratory function by filming blood on both sides of screens which have a somewhat larger mesh than ordinary fly screens. These screens are made of stainless steel wire and are suspended vertically and parallel in a plastic chamber. As the blood flows over these screens, it takes up oxygen and gives off carbon dioxide. It should be remembered that it is equally important to remove carbon dioxide from the blood as it is to add oxygen. It is easy to observe that sufficient oxygen is being picked up in the apparatus, as the blue blood entering the oxygenator becomes red as it leaves. This can be determined more accurately, of course, by intermittent sampling or by continuous reading with a Wood cuvette and oximeter. On the other hand, there is no way of estimating the carbon dioxide tension by observing the color of

Dr. Gibbon is Professor of Surgery and Director of Surgical Research, The Jefferson Medical College, Philadelphia, Pennsylvania.

the blood. We have solved this problem by reading continuously the pH of the blood as it leaves the oxygenator. As there is no significant increase in fixed acids in the blood in the course of these experiments, the pH changes are due practically entirely to changes in carbon dioxide tension. We have an automatic control which keeps the carbon dioxide tension at the desired normal level and which is operated by any change in the continuously recorded pH level of the blood.

A third important feature of any apparatus which temporarily performs the function of the heart and lungs is constancy of fluid volume. The apparatus should at all times hold a constant volume of blood at any rate of blood flow. If the apparatus is not designed so as to hold a rigid volume of blood at all rates of blood flow, blood might accumulate in the apparatus with consequent depletion of the subject's vascular system and a dangerous drop in the subject's blood pressure. Similarly, if the apparatus should hold less blood at any time, there would be an excessive amount of blood in the subject's vascular system. Obviously the tubing in the blood circuit will always hold a constant amount of blood. There are two places in the circuit, however, where the blood volume might vary. One is in the blood reservoirs at the bottom of the plastic chambers which draw venous blood from the subject, and the other is in the thickness of the film of blood on the screens in the oxygenator. Rigid control of the volume of blood at the bottom of these plastic chambers has been obtained by an electronic device invented by Dr. B. J. Miller in our laboratory. This electronic device senses the level of the blood in these chambers and automatically operates the pumps which draw blood from the chambers. Thus when the level of blood tends to rise, the pump automatically operates at a faster rate. When the level falls the pump automatically is slowed. This electronic circuit has proven eminently satisfactory and maintains a rigid volume of blood in these chambers.

In the second place where blood might accumulate, on the screens of the oxygenator, a very simple way to avoid such an increase is by inserting an additional pump in the circuit which draws not only from the bottom of the mechanical lung but also from the tubing carrying venous blood from the subject. This additional pump operates at a rate which is always greater than the rate of blood flow from the venae cavae of the subject. As this pump operates at a fixed rate, the thickness of the blood on the screens in the oxygenator does not vary.

The fourth important requirement of any mechanical heart and lung apparatus is that the apparatus should remove all of the blood returning to the heart through the venae cavae and yet should not apply too great a negative pressure to the orifices of the cannulae because the venae cavae would then be collapsed around the orifice of these cannulae. We have found that the simplest way of obtaining such a smooth blood flow from the cavae is to interpose a suction chamber between the pump and the cannulae in the venae cavae. The degree of negative pressure can be easily regulated in this chamber and a smooth uniform flow of blood is easily obtained.

In summary, then, every mechanical heart-lung apparatus devised to take over temporarily the entire functions of the heart and lungs must comprise four essential features. First, there must be a good method of pumping blood through the circuit which does not cause hemolysis, which can be quickly and easily adjusted to varying flow rates and finally which enables the blood circuit to be easily and thoroughly mechanically cleaned. Second, the mechanical lung must not only fully saturate the blood with oxygen but must maintain the carbon dioxide tension of the blood at a normal level. The latter requirement may be taken care of by an automatic apparatus which continuously reads the pH of the blood leaving the mechanical lung and adjusts the carbon dioxide tension accordingly. Third, the apparatus must hold a constant amount of blood at all rates of blood flow. This can be accomplished by electronic control of the pumps removing blood from plastic chambers so that the pumps operate always to maintain a constant level of blood in the reservoirs at the bottom of the chambers. The thickness of the blood film on the screens in the oxygenator is kept constant by an extra pump which always circulates a constant flow of blood over the screens. Fourth such an apparatus must be able to remove smoothly all the venous blood returning to the heart through the venae cavae without collapsing these veins. We have found the simplest way of accomplishing this is to interpose a negative pressure chamber between the pump and the cannulae in the venae cavae.

There are two problems concerning operations upon the open heart which merit discussion. The first consists in the disposal of the blood returning to the chambers of the heart even though all the blood flow from the venae cavae is diverted to the apparatus. The second problem is the avoidance of air embolism when the heart is opened.

The first problem is not difficult to solve. When the entire functions of the heart and lungs are taken over temporarily by the mechanical heart-lung apparatus, the myocardium continues to receive its normal flow of oxygenated blood by way of the coronary arteries. This blood is returned to the interior of the heart by way of the coronary sinus and the Thebesian veins. This blood must be disposed of so that the operative held can be clearly visualized when the heart is opened. We have accomplished this by aspirating this blood into a special plastic chamber in which any air aspirated is dissipated. The blood collects at the bottom of this chamber and is pumped back into the main extracorporeal circuit free of air.

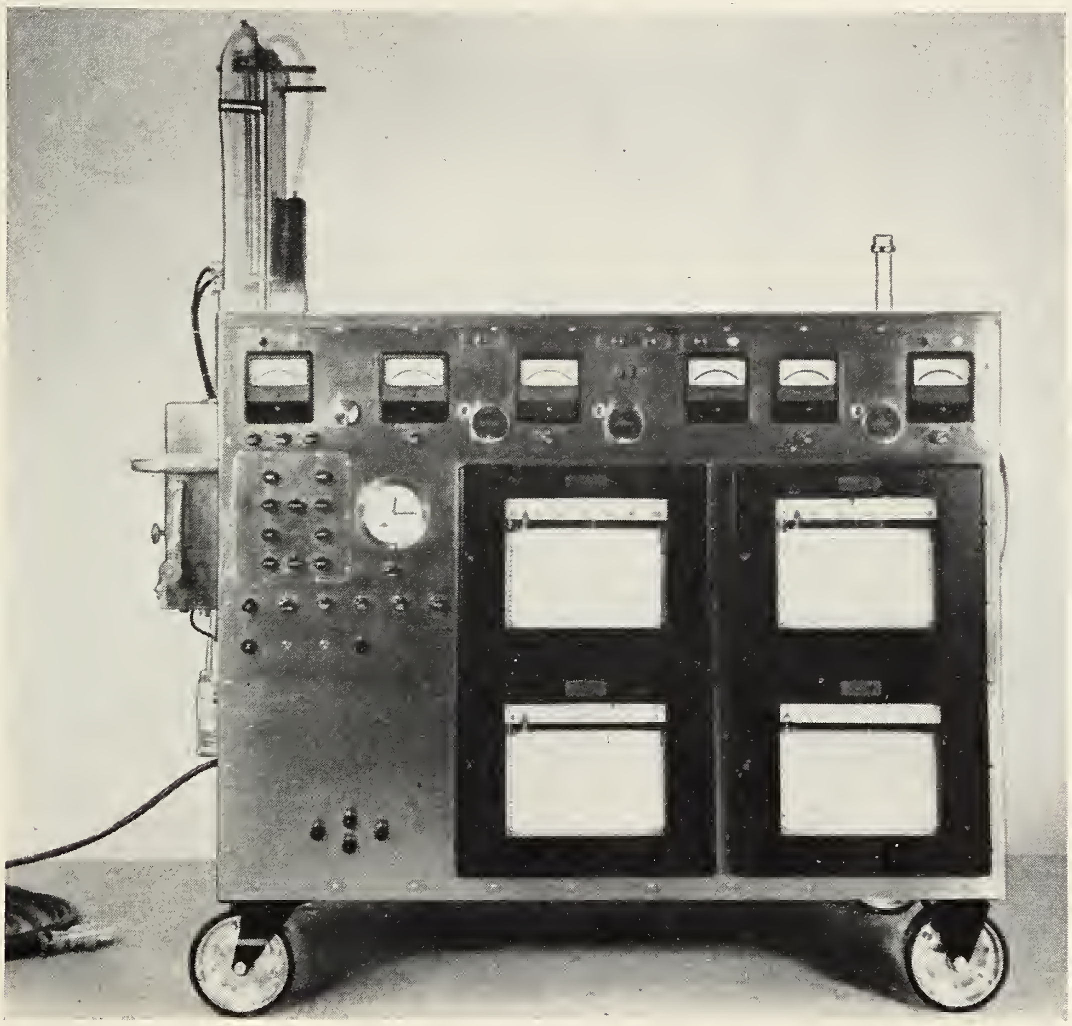

Fig. 1. Front view of apparatus showing the recording and control instruments and the lung suspended above the cabinet on the lett.

Air embolism must be avoided when the heart is opened. If there is no septal defect, operations upon the right side of the heart can be performed without any great danger from air embolism. It is easy to flood the chamber of the heart with blood or salt solution after the operation is completed so as to avoid air embolism. Small amounts of air in the pulmonary arteries are probably not significant. On the other hand, operations on the left side of the heart, or on the right side of the heart in the presence of a septal defect, present a real problem in the prevention of air embolism into the ascending aorta. The immediate result of such air embolism is usually blockage of the coronary arteries with ventricular fibrillation and death. Our solution of this problem is to insert a small plastic catheter through a stab wound in the apex of the left ventricle. Suction is applied to this plastic catheter during the course of the open cardiotomy so that any air or blood entering the left ventricle takes the path of least resistance out through this plastic catheter instead of being

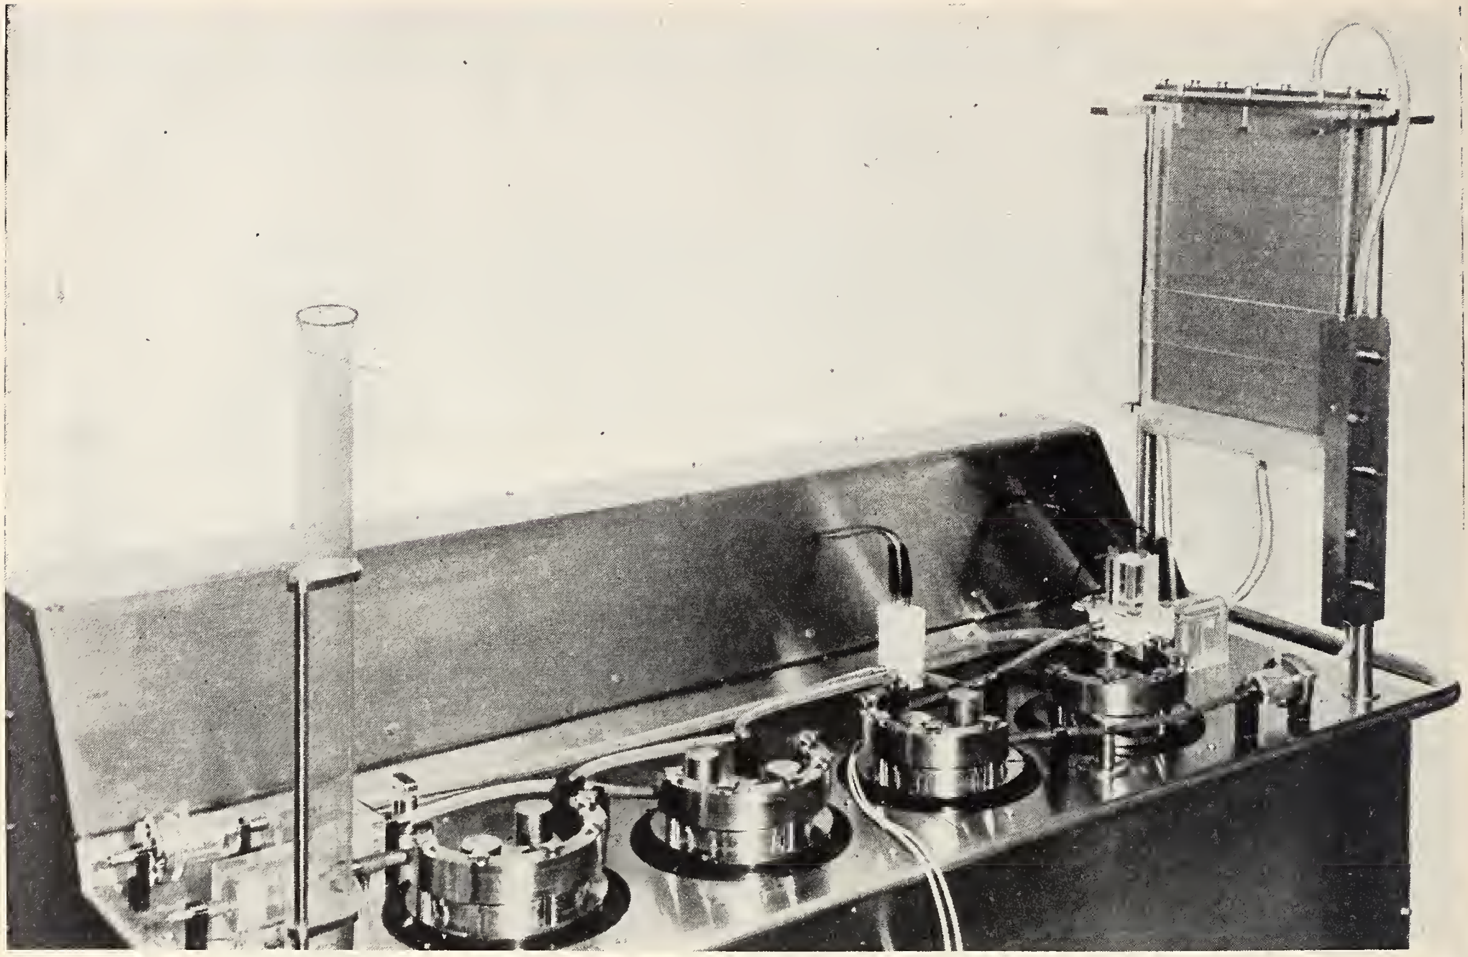

Fig. 2. Oblique rear view of apparatus showing the rotary blood pumps and the battery-type screen lung suspended above the cabinet on the right side.

ejected into the aorta. This plastic catheter is also connected to the debubbling chamber which receives the cardiac venous blood aspirated from inside the heart. Thus this blood is also returned to the circuit, and so to the subject, after the air bubbles are removed. After the wound in the heart is closed, and no further bubbles of air appear in the tubing connected to this catheter, it is removed and the small stab wound in the left ventricle closed by suture. Since employing this method in both animals and patients, we have had no instances of air embolism.

Figure 1 shows the front view of the apparatus which I have described, with the recording and control devices on the front panel. Figure 2 shows the rear view with the roller type pumps on top of the cabinet. Two rollers on a revolving arm pass over the rubber tubing which is clamped in a semicircular position. The rollers move the blood through the tubing and the blood cannot flow back because there is always a roller compressing the tube. To the right of Figure 2 is the mechanical lung which consists of vertical screens suspended in parallel in the plastic case. Blood passes onto the screens through slits at the top of the lung. The blood collects in the bottom of the plastic case as it leaves the screens. The pump returning the oxygenated blood to the subject is automatically controlled by the electronic device which senses the level of the blood at the bottom of the plastic case, through which the blood passes. The lucite block near the oxygenator contains glass and calomel electrodes which continuously measure the pH of the blood. The filter consists of a screen with wires 150 microns in diameter and a 300-micron mesh. We do not know whether such a filter is necessary before returning the blood to the subject. However, we regard it as a good safety precaution in human patients. The tube at the end of the apparatus returns the blood to the patient through a cannulae directed in a central direction in an artery. In human patients we employ the central end of the divided left subclavian artery. The other two tubes are connected with cannula which are inserted into the superior and inferior venae cavae.

Oxygen is blown over the screens suspended in the plastic case. Thus the blood film on the screens is exposed to an atmosphere of pure oxygen. The lung shown in Figures 1 and 2 has six screens. We have a larger mechanical lung with eight screens which are of longer length and which we have used on adult patients. An additional pump draws blood both from the bottom of the oxygenator and from the tubing containing the venous blood coming from the patient. The pump maintains a constant rate of flow through the oxygenator so that there is no variation in the thickness of the films on the screens. The electronic control circuit maintains the blood level in the bottom of the plastic case constant at all rates of flow. The pump removing the blood from this chamber is controlled by this electronic device.

There are two plastic negative pressure chambers. One of them collects the blood from the venae cavae and the other (Fig. 3) is the debubbling chamber in which the blood from the cardiac veins and from the left ventricle is collected. As the blood passes down the sides of this plastic chamber any bubbles of air are dissipated. Last spring we reported the successful repair of interatrial septal defects in animals using a flap of pericardium. We have been prepared to use such a flap of pericardium in human patients. We found, however, as Swan has, that it is quite easy to close such defects with a continuous suture in the open heart under direct vision and that consequently a pericardial graft is not needed.

The inferior vena cava is cannulated by a "tygon" tube passed into the inferior vena cava by way of the right atrial appendage. The superior vena cava is cannulated by a "tygon" tube passed through a stab wound in the right atrial wall. Oxygenated blood from the apparatus is pumped into the aorta through the divided central end of the left subclavian artery. Ligatures passed around the superior and inferior venae cava are tied over the enclosed cannulae. This diverts all the venous blood to the extracorporeal blood circuit. In addition to closing atrial septal defects in dogs with the pericardial graft, we have successfully closed interventricular defects in dogs by direct suture. The defect is exposed by an incision in the anterior wall of the right ventricle parallel to the left anterior descending coronary artery.

There has been a progressive decline in operative mortality in successive series of animals operated upon in our laboratory. Three years ago we had an 80 per cent mortality. In the most recent series this mortality has declined to 12 per cent. By operative mortality we mean any death which could be attributed to the operation and any death occurring the first month after operation. We have successfully temporarily taken over the entire blood flow through the heart and lungs of a dog for as long as one hour and forty minutes with prolonged survival in a healthy condition.

The average saturation of the venous blood entering the apparatus is 63 per cent. We regard a normal saturation of venous blood with oxygen as the best indication of an adequate blood flow to the tissues. If the saturation of venous blood with oxygen falls to low levels it is obvious that there is an inadequate blood flow to the tissues. We have been successful in maintaining the pH in a normal range. The hemolysis in this group of experiments averaged 35 mg. of free hemoglobin per hundred ml. of plasma. You are all aware that this is an insignificant amount of hemolysis and that a similar degree of hemolysis can occur if blood is forced rapidly through a fine needle. There is only slight increase in the fixed acids, generally in the neighborhood of three millimoles per liter which is within the normal diurnal variation.

Now I suppose what you are all interested in is not how many animals we have successfully operated upon but how many humans we have operated upon. The details of our animal experiments have appeared in two articles recently published. The human patients we have operated upon, using the apparatus, have not yet been reported.

We have used the apparatus to carry temporarily the entire cardiorespiratory functions of four human patients. The first was operated upon a year and one-half ago, and the last in July, 1953, of this year. We have one surviving patient who is quite well in every way with complete closure of an atrial septal defect. The three deaths have all been due to human error and not to failure of the apparatus.

The first patient, who was operated upon a year and one-half ago, was a fifteen-month-old baby that weighed eleven pounds and was in severe congestive cardiac failure. Attempts at cardiac catheterization in this baby were unsuccessful. It was the opinion of everyone who saw this baby that the cardiac abnormality was an interatrial septal defect. We explored the right side of the heart using the apparatus and discovered that no atrial septal defect existed. The child died after operation and at postmortem was shown to have a huge patent ductus arteriosus which had not been recognized at the time of operation. This, of course, illustrates the importance of complete exploration of every heart which is operated upon. We might have saved this child's life if we had closed the ductus.

The second patient was operated upon May 6, 1953. She was an eighteen-year-old girl who had a large interatrial septal defect proved by cardiac catheterization. The patient had been symptom free until about six months before operation, when she began to show symptoms of right- sided heart failure. She was hospitalized three times in these six months. Every time she returned to ordinary activity, she had symptoms of heart failure. Cardiac catheterization revealed an atrial septal defect with a left to right shunt through the defect amounting to nine liters per minute. The patient was connected with the apparatus for forty-five minutes and for twenty-six minutes all cardiorespiratory functions were maintained by the apparatus. She had a large interatrial septal defect which was quite easily closed with a continuous silk suture. The patient's postoperative convalescence was uneventful. She was readmitted to the hospital in July, 1953. At this time, cardiac catheterization showed that the septal defect was completely closed and that there was no evidence of any shunt. The cardiac murmur had completely disappeared and she was in good health. We believe that a transverse incision extending from one axilla to the other opening both pleural cavities through the fourth interspace, and dividing the sternum, gives the best exposure for this type of cardiac operation. The chest wound heals quite solidly and results in an inconspicuous scar beneath the breasts.

The last two patients were operated upon in July, 1953. They were both underdeveloped girls aged five and one-half years. Each of them weighed only about thirty pounds. The first child had a large interatrial septal defect proved by cardiac catheterization. Cardiac arrest occurred after we had opened the chest but before we had cannulated any vessels. The heart became blue and dilated as the chest was being explored. We tried for one hour to establish normal cardiac contractions but were unable to do so. We then rather reluctantly cannulated the superior and inferior venae cavae and the left subclavian artery while an assistant massaged the heart. As soon as the patient was connected with the apparatus the heart action became strong and the color of the heart pink. We then opened the right atrium and repaired five separate defects in the interatrial septum. After the defects were closed and the heart wound sutured, the ligatures around the venae cavae were cut allowing the heart to take over part of the circulation. Whenever we stopped the artificial support by the machine, the heart dilated and began to fail. Partial support by the extracorporeal blood circuit was maintained for three or four hours at the end of which time the cannulas were withdrawn and the chest was closed. The patient's heart, however, dilated and cardiac arrest occurred. Death, of course, in the patient cannot be attributed in any way to the use of the heart-lung apparatus as cardiac failure occurred prior to the use of the apparatus. Perhaps the dilatation of the heart and cardiac arrest was the result of a reversal of the shunt through the interatrial defect due to blood transfusion which was given during the early part of the operation.

The second five and one-half-year-old child had a proven interatrial septal defect by cardiac catheterization. It proved impossible, however, to pass the catheter into the right ventricle. On clinical grounds an interventricular septal defect was thought to exist in addition to the interatrial defect. It was known that the patient had a left superior vena cava which was somewhat larger than the right superior vena cava. The child turned out to have not only a huge interatrial septal defect but also a large interventricular septal defect and a small patent ductus arteriosus. Cannulation proceeded normally in this child and when we opened the right atrium we found it to be flooded with bright red blood returning to the atrium through the tricuspid valve. Ae we could not get a clear field to work and the flow of bright red blood was so excessive, we closed the atrium and removed cannulae. The child died after the operation, which was to be expected due to our failure to correct any of the cardiac defects.

(Motion picture shown)

This motion picture was taken during the course of the operation in which the five separate interatrial defects were sutured. It illustrates the value of being able to visualize the interatrial septum. It seems to me that the four smaller defects might have been missed by the employment of indirect blind methods. The film clearly shows how simple it is to keep the operative field clear of blood and that the heart appears of normal color and is beating well because the myocardium is receiving oxygenated blood from the apparatus through its coronary vessels.

In conclusion, I would like to say that I think the work I have reported is some of the early work in this field and that there is considerably more work to be done. It seems to me that there will always be a place for an extracorporeal blood circuit because it permits a longer safe interval for opening the heart than can ever be obtained by any of the hypothermia methods.

Discussion

Dr. F. D. Dodrill, Detroit, Michigan—You have just heard an excellent review of the mechanical heart work by the leading pioneer in this country. Dr. Gibbon has had vastly more experience than the rest of us in this field, and I am envious of his vast accomplishments in this work.

When I first began this work several years ago, it was not definitely known, nor is it now definitely known, just how this can best be done. It was originally thought by those working in the field one could not bypass either side of the heart without completely bypassing the entire heart and lungs at the same time. As time has gone on and various workers have made definite contributions along this line, it is now apparent that either the right side or the left side of the heart may be bypassed while the opposite side of the heart and lungs continue to perform their functions.

We began a few years ago, therefore, to explore the possibilities of the following types of procedures: (1) bypass of the right heart, (2) bypass of the left heart, (3) bypass of both sides of the heart using the lungs for oxygenation, and (4) bypass of the heart and lungs using the mechanical oxygenator. We have performed more than 100 operations on the experimental animal doing one of these various procedures.

Our apparatus is so constructed that it can perform any or all of these functions. Insofar as the mechanical heart itself is concerned, I feel there are three factors which are important. These are: (1) it should be strong, sturdy and not subject to breakdown, (2) it should be so constructed that all parts coming in contact with the blood can be sterilized by ordinary autoclaving, and (3) it should produce and maintain a pulsatile flow in the vascular system.

Bypass of the Right Heart.—Our experimental work in bypass of the right heart has been highly successful in the experimental animal. This consists in taking the blood from the superior and inferior vena cava, passing it through the right side of our mechanical heart and back into the pulmonary circuit through the artery to the right lower lobe of the lung. By this method, the right side of the heart can be bypassed while the opposite side and the lungs continue to perform their functions. Also, if one wishes, the blood may be taken from the right atrial appendage. By this method not only the superior and inferior vena cava flow, but the coronary sinus flow, as well, can be completely diverted from the right side of the heart. These connections depend upon the type of procedure and the exposure which one is attempting.

In our experimental work on the right-sided bypass, we encounter severe hypotensive reflexes. These hypotensive reflexes are greatly increased by even the slightest degrees of anoxia. This reflex has been referred to as the Bainbridge reflex but it may be possible, that additional reflexes may be present. It is my impression that a great deal of physiological investigation is needed along this line. On the left side, however, these hypotensive reflexes are much less acute and oftentimes in the experimental animal we see no evidence at all of a decrease in the blood pressure during a left-sided bypass. Using such a procedure, any purely right-sided heart disease may be exposed and corrected under direct vision. The examples of such conditions are pure pulmonary stenosis with an intact cardiac septa and diseases of the tricuspid valve also with an intact septa. Figure 1 illustrates the pulmonary valve in a patient with pure pulmonary stenosis during a right-sided bypass. This valve was exposed for a period of twenty-five minutes while the mechanical heart pumped approximately 4½ liters of blood per minute. The left side of the heart continued to perform its function as did the lungs. While the right-sided bypass of the heart seems to be a rather practical procedure, it should be pointed out that there are not many pathological conditions of the right side of the heart alone in which such a procedure can be used. The great majority of patients with pulmonary stenosis have a defect in either the intratrial or interventricular septum and in such a patient a unilateral bypass is, of course, out of the question. There are rare instances of large emboli lodging in the right side of the heart which give some warning before death and it is possible that such large emboli could be removed during a right-sided bypass.

A right-sided bypass is a practical procedure for patients with pure right-sided disease. There is no need at all for bypassing the lungs as well for exposure of a purely right-sided defect. The main advantage of using the mechanical lung along with the mechanical heart is that the connections of the apparatus to the anatomical structures are much easier. However, with a right-sided bypass, the connections are likewise easy and should present no obstacle at all to the operating surgeon. Of all these various procedures which can be done in the way of

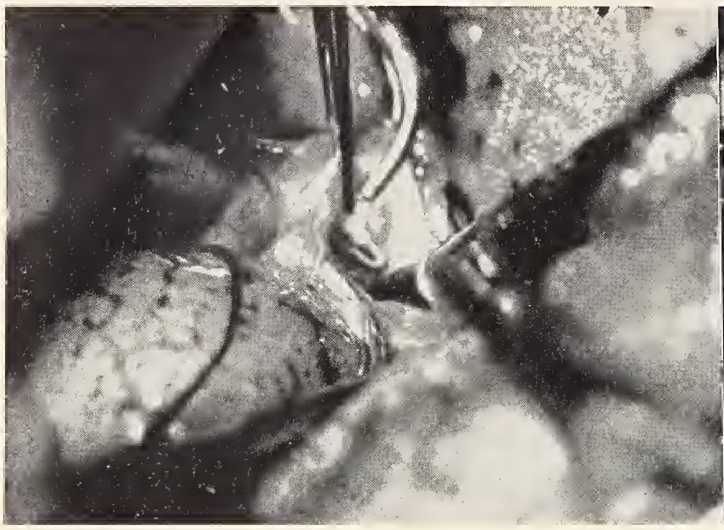

Fig. 1. Stenotic pulmonary valve in a seventeen-year-old boy.

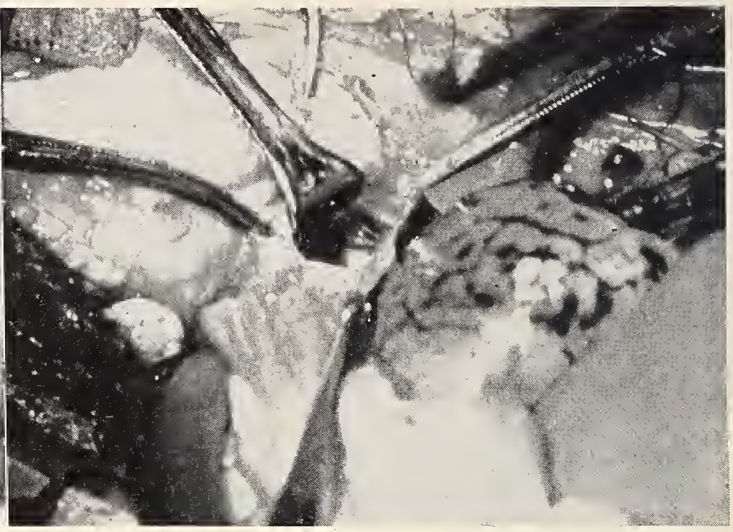

Fig. 2. Open left strium exposing the mitral valve in a fifty-year-old woman.

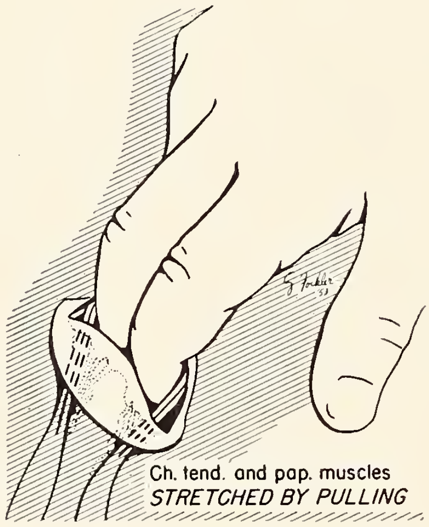

Fig. 3. A method of elongating the chordae tendineae in a patient with mitral regurgitation.

bypassing the entire heart or a portion thereof, I strongly feel that a right-sided bypass alone is a practical procedure which will be useful in years to come. The pathological conditions, however, are rather limited for this type of a procedure.

Bypass of the Left Heart.—A great deal of animal experiments have been done on the left-sided bypass. This consists in taking the blood from the pulmonary veins, passing it through the left side of the mechanical heart and back into the aorta which is its ultimate destination. The experimental work on dogs is extremely gratifying. We have been able to expose the mitral valve in dogs for fifteen consecutive times without a fatality. During the left-sided bypass, the right side of the heart and the lungs continue to perform their functions. During such a procedure, it is necessary to maintain a sufficient systemic blood pressure and preferably to maintain it by a pulsatile flow. The hypotensive reflex which is rather acute on the right side, especially if there exists any degree of anoxia, is not so acute on the left side. In numerous animal experiments, we have not encountered such a reflex at all. We have applied this procedure to a few patients. Figure 2 illustrates the open left atrium with the mitral valve in the depths of the cavity. This patient made an uneventful recovery and is much improved from the surgical procedure. It seems logical to assume that if the mitral valve can be exposed, there is more apt to be an opportunity to improve valve function especially in mitral regurgitation. Figure 3 illustrates the elongation of the chordae tendineae in a patient with mitral regurgtation during a left-sided bypass. Although, the valve and the chordae were not visualized, the arterial pressure pattern shows conclusively that the mechanical heart was completely maintaining the systemic circulation. It has now been over one year since this patient was operated and he is vastly improved, even to the point of almost a complete disappearance of his loud murmur. One additional patient has also been treated in a similar manner with encouraging results. There are several factors in the production of mitral insufficiency; however, the most important one seems to be the shortening of the chordae tendineae and sometimes the papillary muscles as well. The valve leaflet itself may be nearly normal, and if the chordae can be lengthened to the point where it permits valve closure, the regurgitation is markedly diminished or corrected. Oher types of procedures have been done during a left-sided bypass. The aortic valve may be manipulated by inserting a finger into the left atrial appendage down through the mitral valve and upwards through the aortic valve. A patient with aortic stenosis has been so treated and the valve was easily fractured with the finger. Whether or not this procedure will be better than the method of going directly through the left ventricle remains to be seen.

Bypass of Both Sides of the Heart.—A bypass of both sides of the heart using the lungs for their natural functions is a more difficult procedure from the technical standpoint. We have been able to do this, however, quite satisfactorily in experimental animals and have applied it to one patient. Both sides of the heart were completely taken over by the mechanical device. A stenotic pulmonary valve was corrected and the interventricular septum was exposed. Unfortunately, this patient had, in addition to the pulmonary stenosis, marked infundibular stenosis and could not be sufficiently corrected. During the course of the procedure, the systemic blood pressure as well as respiratory function were quite satisfactory. Unfortunately, the patient succumbed on the fourth postoperative day from atelectasis and pneumonitis.

A Combination of Hypothermia and the Mechanical Heart.—These various procedures which I have shown you have been done solely with the mechanical heart. We are now working along the lines of the combination of hypothermia and the mechanical heart. Whether or not various types of intracardiac surgery will be done under hypothermia alone, using the mechanical heart alone or a combination of these two methods remains to be seen. The advantage of combining hypothermia with the mechanical heart is that during hypothermia, the circulating blood volume is markedly reduced and the work of the mechanical heart is vastly decreased. Moreover, with the circulation of such a small volume of blood, only one lobe of the lung needs to be used for respiration. Such a small quantity of blood can be easily circulated through one lobe of the lung while the rest of the lungs are at rest. This vastly minimized the technical difficulties with the use of the mechanical heart alone. It is easy to cannulate one of the upper pulmonary veins, to pass the blood through the left side of the mechanical heart and back into the aorta. The right-sided connections for such a procedure are similar to a complete bypass of the heart and lungs and consists simple of cannulating the superior and inferior vena cava and passing the blood back into the pulmonary circuit. The lung is a very intricate organ. It is not known but that it may perform other functions aside from the uptake of oxygen and the release of carbon dioxide. It seems as though a good hard attempt should be made at using the lung for its natural function before we completely discard it.

Dr. Clarence Dennis, Brooklyn, New York.—After Dr. Maurice D. Visscher and Dr. Owen H. Wangensteen jointly suggested to me, late in 1945, the undertaking of a project to develop an artificial heart-lung apparatus, I very quickly became aware of the activities of Dr. John H. Gibbon, Jr., and his group in Philadelphia. I consulted him at that time, and was very cordially received, shown protocols, shown the apparatus as it had developed up to that time, and welcomed into the group of those working on this project. Between that time and this, there have been associated in the research project with Dr. Karl E. Karlson and me approximately eighteen physicians. Work has been carried out first at the University of Minnesota and more recently at the State University of New York, and has been supported by the United States Public Health Service, the Graduate School of the University of Minnesota, the State University of New York, the Life Insurance Medical Research Fund, and private sources. In our search for an answer to this problem, my associates and I have come to have the very highest regard for the ingenuity, integrity, and cordiality of Dr. Gibbon and his associates. Success could not have come to finer people.

Dr. Gibbon has very carefully listed the qualifications of a satisfactory artificial heart-lung apparatus. We have been concerned with an additional qualification, namely, the ability to render the whole apparatus absolutely free of bacterial contamination. The reason for our preoccupation with this qualification arises from the work of Dr. Russell M. Nelson, who was a member of our research group three years ago. Dr. Nelson showed that our apparatus at that time was contaminated with the paracolon bacillus, and that injection intravenously into normal dogs of a re-suspended fourteen-hour culture of this organism resulted in a symptom complex which had been responsible for most of the deaths prior to that time. This symptom complex developed rapidly and killed some dogs in less than three hours. The affected dogs showed a rapidly progressive metabolic acidosis, an incoagulable state of the blood, development of effusions into the serous cavities, massive gastrointestinal hemorrhage, and death in shock.[3] Satisfactory sterilization of the apparatus removed this symptom complex from our list of problems. The machine which we formerly used could not tolerate autoclaving, and sterilization by formaldehyde proved fairly regularly to be incomplete. Nevertheless, it was possible for us to do a long series of animal perfusions with this old apparatus, with no more than a 10 per cent mortality attributable to the perfusion *per se*.[1]

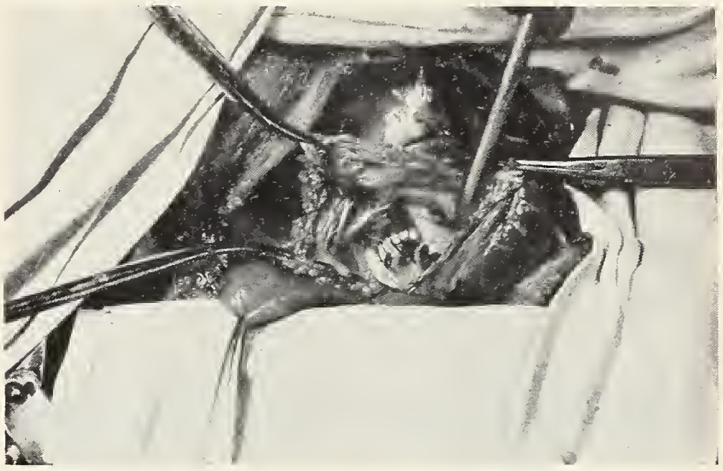

Fig. 1. Closure of inter-atrial septal defect, May, 1951. Closure was easily performed with interrupted silk sutures under direct vision. The patient suffered air embolism before opening the atrium, a consequence of human error in failure to switch on an automatic control mechanism. She died of complication of air embolism after several hours of partial support by the machine.

We gained so much confidence with this apparatus that, in conjunction with Dr. Richard Varco, we perfused two patients in efforts to achieve satisfactory closure of inter-atrial defects.[2] We were unsuccessful in salvaging either of these patients, but it was the consensus that the failure was not due to any intrinsic defect in the apparatus, but rather to human errors. The repair which was accomplished in the second patient is shown in Figure 1. This patient was lost as a consequence of human error, namely, failure to turn on the automatic control apparatus, which had been designed and proven adequate to maintain the desired blood level in the reservoir of the oxygenator. Air embolism occurred because of this oversight. The patient survived approximately eight hours after the procedure, but only by virtue of partial support by the pump-oxygenator, and the closure at the time of autopsy was perfectly adequate. Dr. Gibbon's observation is in agreement with ours, namely that the margins of most inter-atrial septal defects in clinical patients are thick, and firm, and silk closure, therefore, is not usually difficult of accomplishment. Closure in this instance, in the summer of 1951, was very easily accomplished.

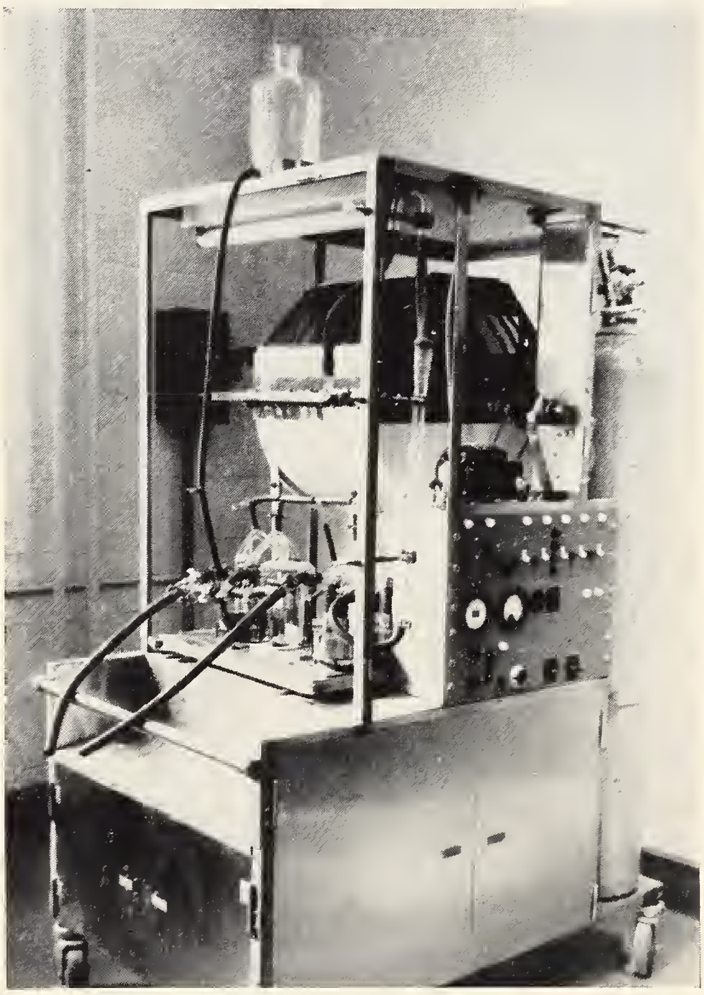

Fig. 2. The present pump-oxygenator apparatus. The entire blood-bearing unit can be autoclaved after assembly. Oxygenation is accomplished by filming on steel mesh discs which are mounted on a rotating horizontal shaft. The pumps are a modification of the Dale-Shuster pattern. Risk of human error has been reduced by use of largely automatic controls.

Because of our concern over the occurrence of human errors and because of our concern with regard to absolute sterility, we have spent the past year and a half in the construction of a new apparatus, the blood-bearing portion of which can be assembled and autoclaved as a unit. This apparatus is not yet complete, but has reached a stage of construction which has permitted us to employ it for approximately two dozen trial perfusions. The apparatus in question is indicated in Figure 2. In this apparatus, oxygenation is accomplished by the filming of blood near the center of a 50 cm. disc of stainless steel mesh which is mounted on a slowly rotating horizontal shaft. It will oxygenate 500 to 600 cc. of blood per minute from half saturation to full saturation and has a volume content of approximately 65 cc. of blood at any given moment. The pumps are a modification of the Dale-Shuster pattern. They are activated by hydraulic pressure, which is produced by a mechanical cam and bellows arrangement below the surface of the table. The apparatus as a whole will handle about 5 liters of blood per minute. It has been calculated that it should be capable of adding in excess of 350 cc. of oxygen per minute and in perfusions in large dogs has been measured to add 210 cc. per minute. We now regularly observe sterile blood cultures at the end of perfusion, and hemolysis produces approximately 1 mg. per cent of plasma hemoglobin per minute of perfusion.

There are many problems which remain and which are the source of considerable concern at the present time. It has been found that our greatest problem is that of postoperative hemorrhage. A technique of protamine titration, which has been employed over a period of several years in our laboratory, indicates that the addition of protamine to the animal is effective for only an hour or two and that additional protamine thereafter must be added until approximately six hours have passed. The platelet count is not appreciably lowered, and this, therefore, is not the reason for our hemorrhagic difficulties. It is suspected that there is excessive trauma to the blood which may be responsible for the degree of hemorrhage which we have experienced, but the low plasma hemoglobin concentrations cast a doubt even on this suggestion. Preliminary studies suggest fibrinolysin as the offender.

Perhaps our major remaining problems with the new machine rotate around the completion of satisfactory automatic controls. We have, at times, utilized the suggestion of Professor Dogliotti of Turin, Italy, that the pumping of blood from the machine to the arterial system of the subject be governed entirely by the arterial blood pressure of the subject. At other times, we have maintained a constant volume in the extra-corporeal circuit. The latter appears to be the preferable arrangement. As far as controls are concerned, the removal of blood from the venae cavae has been simplified by setting the apparatus up in such fashion that the pumps fill by gravity from the vena cava.

There remain several metabolic problems that have to be studied. An occasional perfusion is characterized by a profound loss of circulating plasma sodium. An occasional perfusion is also complicated by development of marked metabolic acidosis, even when there is a negative blood culture. Finally, there is occasionally a profound disappearance of circulating protein, which, as yet, we have not been able satisfactorily to explain.

It is likely that Gibbon has better solutions to many of these problems than we, but all of them must be painstakingly resolved before utilization of pump-oxygenators in clinical surgery can become general.

APPLICATION OF HYPOTHERMIA TO CARDIAC SURGERY

W. G. BIGELOW, M.D.
Toronto, Ontario, Canada

THIS REPORT contains a brief review of our early work on the physiology of hypothermia. Following that an assessment is made of the present status of research on hypothermia and some aspects of its clinical application to cardiac surgery are discussed.

General hypothermia is being investigated as a means of reducing the oxygen requirements of the body sufficiently to allow exclusion of the heart from the circulation and thus permit intracardiac surgery under direct vision. Ordinary adult laboratory animals cannot be cooled safely to a body temperature much below 20°C. These studies are concerned with changes between 38°C. and 20°C., during surface cooling and rewarming.

In dogs, the oxygen consumption steadily declines with a fall in body temperature, provided the shivering reaction is carefully controlled and arterial oxygen saturation maintained. At 20°C., it is approximately 15 per cent of normal. The picture on rewarming is much the same, with a similar gradual increase in oxygen consumption as the body temperature rises.

In cardiovascular studies, the blood pressure fell slowly to approximately 24°C., below which temperature, the fall became more rapid. Heart rate and cardiac output showed a more progressive fall during cooling. The cardiovascular state returned to normal on rewarming. The venous pressure rises slightly during cooling. If the positive pressure artificial respiration is vigorous and over a long period there is a greater rise in venous pressure. The electrocardiogram shows typical changes and reverts to normal on rewarming.

We have been asked whether low body temperatures may not have a deleterious effect upon cerebral function. In continuous electro-encephalograms in monkeys the waves diminished and there was often no evidence of cortical activity at 20°C. There were no wave forms suggesting cerebral anoxia and normal tracings re-appeared on rewarming. Behavior tests before and after cooling, showed no evidence of cerebral damage. These tests were not repeated following a period of interruption of the circulation.

In the biochemical study there were no serious electrolyte changes noted with our original cooling techniques. Small changes in potassium and calcium were not considered significant, although an increase in potassium sensitivity at low body temperature has already been reported in the literature.

It was known that low body temperatures cause a shift in the oxygen dissociation curve to the left and presumably the oxygen becomes less available to the tissues. In order to offset this, the CO_2 content of the blood, originally, had been increased during cooling and a pH slightly below normal was maintained in order to balance this effect. In a complete study of the acid base mechanism, it was found that the pH of the blood could be varied depending on the rate of positive pressure artificial respiration with pure oxygen during cooling. Contrary to our original premise, the animals appeared to tolerate low body temperatures with greater safety if their pH was maintained above normal. This was judged by a reduced incidence of cardiac arrest on cooling a series of animals to 18°C.

During actual surgery on the heart at low body temperatures it was a difficult situation to find oneself with the chest open at low body temperature and the heart in standstill. It is awkward and impractical to rapidly rewarm an animal with the chest open. Primarily to meet this situation, an electrical artificial pacemaker was designed which stimulates the sino-auricular node through an intravenous electrode producing heart beats with sustained blood pressure. This makes it possible to close the chest and rewarm the animal to a temperature where his own nodal rhythm will return. This electrical pacemaker has been combined with a defibrillator in a single resuscitation unit and has been in use experimentally and clinically for over two years.

As a further development of the technique of

Presented in the Symposium on Recent Advances in Cardiovascular Physiology and Surgery, University of Minnesota, Minneapolis, September 16, 1953.

Dr. Bigelow is Assistant Professor of Surgery, University of Toronto.

This work has been supported by a grant from the Defence Research Board of Canada.

resuscitation from low body temperatures, a radio-frequency technique of rewarming was designed. It had been felt that this may be more practical in the operating room of hospitals, particularly when dealing with adult patients and would very likely prove an advantage from an esthetic point of view. The chief reason for developing this method for rewarming of animals however, was an attempt to prevent the "rewarming shock" which often developed upon rewarming in water at 40°C., and for which no adequate explanation, as yet, has been given. This is an inductive type of heating in which the animal or patient lies between two insulated coils. This produces a simultanous rewarming of deep and superficial structures and is an attempt to prevent premature dilation of the peripheral vascular bed.

In applying this principle surgically, our earlier results with dogs were only moderately encouraging. In a later series, using monkeys that had been cooled to a body temperature of 17°C., to 19°C., it was found possible to exclude the heart from the circulation and open it for fifteen to twenty-four minutes, with survival in twelve or thirteen experiments. Since these animals showed no changes in personality or behavior after this experience, it was judged that there had been no serious ill effects to the cerebral function. In this series of experiments a small amount of Pentothal anesthetic was given intravenously and they were cooled by being placed in cooling blankets containing coils with circulating refrigerant and 0°C. They were removed from the blankets about 2°C., above the temperature at which the operation was to be performed, as there is always a drift down following removal due to the temperature gradient which exists with surface cooling. With experience this drift can be assessed beforehand as it appears to depend upon two factors, namely: (a) the rate of cooling and (b) the weight of the animal or patient.

Both the right and the left side of the heart were opened in these experiments. They were merely token procedures and no specific intracardiac maneuvers were carried out. The field was dry at that temperature and the coronary inflow, which is a serious technical problem with the extracorporal technique, is at a minimum and usually represented by a slow ooze. This of course is because the arterial blood pressure is not maintained during the period which the circulation is interrupted.

Both the warm water and the radio-frequency technique of rewarming were used and the rate of rewarming in each is about equal. These animals were active within two hours of their return to normal body temperature. There appeared to be a higher incidence of wound infection than one would expect from a similar series of thoracotomies at normal body temperature.

Hibernation.—In all this work, the limiting factor in general hypothermia has been the development of cardiac arrest as either venticular fibrillation or cardiac standstill in adult dogs and other laboratory animals once the body temperature falls below 20°C. Even a body temperature of 20°C., is not completely safe in dogs. On cooling a series of adult dogs at this temperature, with positive pressure respiration, a small percentage will die of cardiac arrest before they reach that level. The statistical results in such a series will depend upon the breed and size of the dog, and in laboratories where the animal cages are not in properly air-conditioned rooms, the results may vary with the season of the year. One may expect better results from cooling, if the animal has been living in a cold environment.

By far the most important factor is age. Young animals display a much better tolerance to low body temperatures and Adolph has shown that infant animals may be cooled to temperatures as low as those that are tolerated by hibernating animals (3° to 5°C.). We have cooled a ten-week-old puppy to 10°C., with survival, so it would appear that animals and very likely humans, lose this tolerance to low body temperatures as they mature.

These facts have afforded a stimulus to investigate ways of recapturing this early characteristic. Evidence is available which indicates that infant humans possess a similar remarkable tolerance to low body temperature which presumably is lost with age and maturity.

For several years our team has tried various biochemical agents and technical procedures in order to make cooling to low temperatures a safe procedure and eliminate the complication of cardiac arrest. These many tedious experiments have met with only a limited improvement in our technique of cooling.

As another approach to the problem, a study of hibernation was initiated. The groundhog will not only hibernate at body temperatures as low as 3°C., but he can be artificially cooled to this level using an anesthetic and a cooling blanket as previously described. At this temperature the circulation was interrupted and the heart opened for one to two-hour periods on six groundhogs with five survivals. In an attempt to discover the secret of this unusual tolerance to low body temperatures, biochemical studies were made of the blood, both at normal body temperatures and during stages of hibernation. These blood samples were taken by special techniques in which the animal was not disturbed. No significant biochemical changes of the order which might explain the above phenomena were found in the groundhog's blood. Thus, his unusual cold tolerance has been attributed to an hibernating gland.

Studies of this gland would indicate that it is an endocrine gland of considerable size, rather than a storage gland, and histologically somewhat resembling the adrenal cortex. There were two large discrete segments of gland in each axilla, but it is also diffusely placed throughout the chest and mediastinum which renders it technically impossible to de-gland the animal. By cooling groundhogs at various seasons of the year and correlating the results with the size of the hibernating gland, a relationship between the activity of the gland and the animals' ability to tolerate very low temperatures, has been found. We have been in the process of extracting this gland for the past two years in the hope of obtaining an active principle which will improve cold tolerance when injected into non-hibernating animals and into human beings.

Present Research in Hypothermia

The present-day experimental approach to the problem of direct vision surgery of the heart is being studied with the use of: (1) extracorporal circulation, (2) hypothermia, (3) a combination of extracorporal circulation and hypothermia. Those studying hypothermia are lowering the body temperature of animals and humans by (a) surface cooling, (b) extracorporal direct cooling of blood, with, or without, the use of a pump. The goal of this research in hypothermia, is to bestow upon ordinary laboratory animals the unusual cold tolerance of hibernating animals that enables them to be cooled safely to very low temperatures. These low temperatures would then allow a longer period of interruption of the circulation and permit the correction of some of the more complicated lesions. At the present time there are only a limited number of conditions which may be corrected by direct vision surgery in five or ten minutes and such a period usually allows very little leeway. In order to obtain longer and safer operating time one has to eliminate the danger of cardiac arrest which develops in adult animals below 20°C., and in young animals at a lower temperature.

One can vary the biochemical state of the animal by various chemicals, cardiac drugs, gland extracts, et cetera. One may also vary the physiological state by technical procedures such as balloon obstruction of the aorta to improve coronary and cerebral flow, irrigation of the coronary arteries during the period of exclusion with a double lumen arterial catheter, the electrical pacemaker, exsanguination and retransfusion, and many other approaches. These procedures often improve the cooling technique and they have reduced but not eliminated the danger of cardiac arrest at these lower body temperatures.

It may be that one may not be able to control ventricular fibrillation and cardiac standstill without a clear understanding of such fundamental problems as oxygen transfer from blood to tissues and nerve conduction at low body temperatures. Infant animals and hibernating animals may have a similar type of tissue metabolism which may require study.

It may be possible to rapidly cool animals to a very low temperature and disregard ventricular fibrillation, with the establishment of a normal heart action on rewarming. This would not be possible in large animals or adult human beings without recourse to the extracorporal circulation.

Clinical Application of Hypothermia

Regarding the clinical application of hypothermia to cardiac surgery, there would appear to be two main conditions where cooling may be useful: (1) to allow intracardiac exposure with obstruction of the circulation and (2) as an adjunct to render current surgical procedures upon the heart more safe.

Doctors Lewis and Varco of this city (Minneapolis) were the first to report a case of intracardiac surgery with hypothermia and it was very pleasant to hear this confirmation of a theory. Several other centers have reported the clinical use of hypothermia for intracardiac surgery since that time. Swan has given further impetus to this work by his experience with experimental hypothermia and his excellent case reports.

Regarding the selection of cases for intracardiac surgery, judging from experimental evidence, one would be well advised to select only infants and children for cooling to the low body temperatures that are required. In order to justify the risk of severe cooling, one must cool to a temperature which allows an adequate period of interruption of the circulation without encroaching too closely on the lethal time limit. With careful cooling of body temperatures to 20°C., the circulation may be interrupted for approximately fifteen minutes. We have found that in infants and children 24°C. to 26°C. is safer, but of course that would allow a shorter period for exclusion of the circulation, perhaps five to ten minutes.

As one examines all of the cases of congenital heart disease in children, from the point of view of surgical correction, they appear to fall roughly into three main categories. (a) There is the very large group of children with congenital heart disease that usually die within the first year of life. In this group one finds tricuspid atresia, transposition of the great vessels, abnormal pulmonary venous drainage, and other similar conditions. These cases will require complicated procedures which cannot be done in a few minutes, but due to their age, they will very likely tolerate low body temperatures better than most cases and with a hopeless prognosis, one feels justified in exposing them to a procedure with a considerable risk. (b) There is the group of ventricular septal defects with, and without overriding the aorta, that will undoubtedly pose a difficult technical problem in many instances due to proximity of the conducting mechanism of the heart. (c) Inter-auricular septal defects and simple pulmonary stenosis, particularly the valvular type, are instances of congenital lesions which are relatively simple to correct and this may be done associated with a short period of interruption of the circulation. The results in cases with valvular pulmonary stenosis will have to be compared with those using the current operative procedure, before this approach can be fairly assessed.

Since age is an important factor in cold tolerance, I should think that the premature patients and infants to a few months of age with congenital heart disease, may be found to demonstrate remarkable tolerance to low body temperatures. If that is the case, one may hope to interrupt the circulation for longer periods of time.

We have commenced our clinical study with infants of the first group in co-operation with Drs. W. T. Mustard and J. D. Keith. The behavior of these infants at low body temperature has been gratifying, but serious obstacles have been met in the technical repair of these complicated cases.

The use of hypothermia as an adjunct to ordinary anesthesia is not new and has been practiced by Dr. Wills Potts for several years. In adults and children facing ordinary cardiac procedures with a high mortality rate due to heart failure or serious arterial oxygen desaturation, the body temperature may be lowered to about 30°C., at which level the oxygen requirements are reduced to about sixty per cent of normal before the hypothermia has seriously reduced cardiac function. This should reduce the risk of surgery. The above figures are based on our oxygen consumption studies and on the fact that in animal work, one finds the pressure fairly well maintained with a gradual fall to about 24°C., at which level it usually drops off rather more quickly. Certainly cooling, both adults and children to 30°C., with proper control of respiration should be a reasonably safe procedure.

In selecting cases for the uses of hypothermia as an adjunct, Mustard and Keith have chosen the very poor risk cases and those that are deeply cyanotic, but for whom a successful operation, by a standard technique, would be expected to yield a good result. Similarly, in adult cardiac surgery, those who are doing mitral valve surgery have found that the mortality rate in the group with right heart failure is high, particularly in the advanced cases with cyanosis and chronic failure. The first such case, in which a significant lowering of body temperature was obtained, was cooled in the sitting position. Her arterial oxygen saturation improved and she tolerated a difficult technical procedure remarkably well. Hypothermia down to 30°C., has proven a worthwhile adjunct in such cases.

One cannot give an opinion as to whether all cyanotic patients undergoing surgery should be cooled. Such a technique in practice may prove cumbersome and time consuming.

One may expect an increased incidence in wound infections with hypothermia. Another complication to be considered is the rewarming shock which has been observed experimentally and may be reduced by the use of our radio-frequency rewarming technique.

Regarding the actual technique of hypothermia, one may suggest rapid cooling in a cold water bath for infants and small children and the use of cooling blankets for larger children and adults. There should be continuous electrocardiogram recordings and rectal temperature.

The infants and children should be anesthetized and intubated before cooling as their cooling period may only be a matter of fifteen to twenty minutes. In the adults, we have cooled them with sedative alone to about 33°C., at which time they are given pentothal anesthesia with intubation and from that point down to 30°C., they are given positive pressure at twenty respirations a minute, in order to blow off excessive CO_2 and maintain a slightly elevated pH. If positive pressure is carried out for too long a period, it is suspected that this may increase the venous pressure and pre-dispose to ventricular fibrillation.

The operative technique has already been mentioned and it is recommended that rapid rewarming be carried out either by warm water at 40°C., or a radio-frequency device to a body temperature of 34° to 35°C. The final three or four degrees rewarming should be carried out in bed with warm water bottles.

Thus, at present, it is felt that hypothermia soon will be made safe for children. Adults cannot be cooled safely to body temperatures which are low enough to permit extensive intracardiac surgery. The answer to the safe cooling of adults may lie in such problems as the release of oxygen to tissues, or in understanding an anerobic type of tissue metabolism possessed at birth which gradually alters with maturity. It is suggested that cyanotic children are already conditioned to low oxygen tensions and very likely possess a slightly different tissue oxidative system. Such children may be expected to cool more safely than those that are not cyanosed.

Regarding the future of hypothermia in surgery, one is still optimistic. Extension of its use to surgery of the aorta is a natural step and many other possible uses such as liver surgery may be found. It requires study and care in its clinical application. Hypothermia as applied to cardiac surgery has, as its greatest asset, its simplicity.

APPLICATION OF A MECHANICAL HEART AND LUNG APPARATUS TO CARDIAC SURGERY (Discussion)

CARDIAC SEPTAL DEFECTS

HENRY SWAN, M.D.
Denver, Colorado

EFFECTS of the two cardiac septa are apparently common, and together comprise a group of congenital heart lesions which is possibly the largest single such group. In 20 per cent of patients with congenital heart disease, one or the other septa will contain a patent defect. The significance to the patient of the presence of a septal opening depends almost entirely upon the volume of blood flow which is shunted through the opening. If this volume is large, an important physiologic defect is created which places its strain upon the heart and affects the size and function of the entire circulatory system.

Ventricular septal defects commonly occur as an isolated lesion as well as part of the complex of tetralogy of Fallot. For some reason which I do not clearly understand, it has become the commonly accepted conception, throughout the medical profession, to associate isolated ventricular defects with the name of Roger, and to think of this lesion as a benign defect which does not need treatment. It is true that there do exist defects of the ventricular septum, usually in the mid-portion of the septum, that though relatively small, do give a systolic murmur, which we should properly classify in our thinking as the maladie de Roger and which, in fact, do not cause significant physiologic disturbance since the shunt of blood is very small. On the other hand, it is our feeling that this is the uncommon type of septal defect. By far the more common and important is the high defect which exists immediately beneath the openings of the aortic and pulmonary valves. In this circumstance, the shunt of blood from left to right is great. There is enlargement and hypertrophy of both ventricles, of the pulmonary artery, and of the pulmonary-vascular bed. A pulmonary hypertension gradually asserts itself in order that systemic flow may be maintained. The strain on the heart now becomes increasingly great and death comes to the patients in the late teens, twenties or the early thirties. The situation is, in our opinion, exactly the same as that described by Eisenmenger and passes under his name in many instances. We do not think that the aorta, in fact, does anatomically override, in most instances, or if it does, is it not displaced by the enlarging pulmonary artery? We wonder whether there is any special entity as Eisenmenger's complex, but rather is it not simply a large ventricular septal defect, with the resultant changes in anatomy and physiology which have been brought about by virtue of this lesion. In any event, a large, high ventricular septal defect creates a functional single ventricle, and the outlook for the patient is no different than it would be were the septum essentially absent.

As for the auricular septal defect, this may occur in two locations, depending on the nature of the embryologic arrest. The auricular septum is formed in two phases with the growth first of what is called the septum primum, followed later by the growth of the septum secundum. Depending upon which process is arrested, the anatomical location on the septum of the defect is determined. Those which occur low, over the openings of the valves, present greater technical difficulty, but both high and low defects present the problem of massive left-to-right shunts of blood with the result of a gradually enlarging pulmonary circulation, that is to say, large right auricle, large right ventricle, large pulmonary artery and pulmonary-vascular bed. At the same time, a corresponding decrease in the systemic circulation occurs so that the aorta is small and peripheral circulation is low. It is thought that this may well explain a rather typical gracile and fragile habitus of patients with this lesion since their systemic circulation is so decreased. The shunt through the auricle into the pulmonary circulation is a saprophytic drain upon the circulatory needs of the remainder of the body. Under these circumstances, the heart gradually enlarges until heart failure ensues. Although we do not believe our computations to be exactly accurate, we have seen pulmonary circulatory flows with indices above thirty, while in the same patients the systemic indices were in the neighborhood of two to three. We think that as much as 75 to 90 per cent of the blood entering the left

auricle may, in fact, escape through the septum into the right auricle. Thus, with auricular septal defects, as with ventricular septal defects, if the lesion is small, the patient may well survive to live a normal life and a normal life span. On the other hand, a very good percentage of these patients come to gradual diminution of cardiac reserve and death in their twenties and early thirties. Because septal defects are common, and because they frequently result in disability and premature death, these lesions are an important challenge to the surgeon to develop safe and adequate techniques for their closure.

As regards ventricular septal defects, the experimental work to date suggests that there is a very critical size which will result in serious physiologic disturbance of blood flow. Holman and Beck[7] were the first, I believe, to study this problem in the laboratory. They noticed that with the creation of defects sufficient to cause a significant shunt of blood, there were marked changes in the size of the heart. They noted the pulmonary artery increased in size until it was quite disproportionate to the aorta, and this was associated with right ventricular hypertrophy. These observations led them to the elaboration of a general thesis, which apparently has stood the test of time, to the effect that the heart and blood vessels place themselves in harmony with the increased volume flow of blood through them. The former, that is the heart, by dilatation and hypertrophy; the latter, the great vessels, by dilatation alone. Eppinger and Gross[4] subsequently studied holes in the septum which measured from 4 to 6 mm. in diameter and by computation determined that from 30 to 50 per cent of the output from the left ventricle went through defects of this size. Subsequently Griffin and Essex[5] determined that a hole in the dog's septum 5 mm. in diameter would close spontaneously, an 8 mm. hole remained and was tolerated indefinitely, but if the lumen were 10 mm., the dog would not survive without digitalization, while one 12 mm. was uniformly fatal within the first eight days no matter what the treatment. This experimental data gives strong support to the clinical impression that the size of the defect and the degree of shunt, is of supreme importance in determining the eventual outcome of the patient.

Experimental methods developed for the closure of interventricular septal defects have so far consisted of attempts to place blindly either autogenous tissues or foreign prosthesis in such a fashion as to occlude the septal opening. Murray[9] described such a method, using strips of fascia lata. Subsequently, Bailey and his co-workers[2] attempted to obstruct the opening by passing pedicled grafts of pericardium, either in the form of tubes or sheets through the septal defect. In their experimental work, both types of pericardial grafts could be placed technically and were tolerated by the heart of the animals who survived operation. In both instances, however, after the passage of a few weeks the grafts melted away and only a strand-like remnant of fibrous tissue remained. Bailey attempted this closure in a few patients with similar results.

Recently, Schumacker[11] has reported a modified method of using pericardial grafts. With this technique, the graft is placed in the form of a tube in a front-to-back fashion within the substance of the septum making the tube traverse the septal defect by means of digital control with a finger through the right auricle into the right ventricle during the placement of the tube. Autogenous blood is now injected into the tube, blowing up that portion which is free within the septal defect into a balloon-like expansion which occludes the opening. In his experimental results, complete closure of the experimental lesion by fibrous tissue resulted from the organization of the clotted blood within the pericardial graft. Schumacker[10] has subsequently modified the technique so that instead of using pericardium, he now uses a tissue made of plastic. He has not yet reported upon the results of his initial clinical trials with this method.

It seems reasonable to believe that the technical problems posed by the interventricular septal defect are somewhat greater than those posed by defects in the auricular septum. The presence of the adjacent conducting tissue of the septum, and the confusion of the immediate environment which includes portions of all four major valves of the heart, have made technical solution to the problems of this particular lesion lag behind that of others. At the present time, I believe it is fair to state that no standardized closure technique of ventricular septal defects is yet available.

Defects of the auricular septum on the other hand, although posing interesting problems, have become amenable to surgical repair at reasonable risk rates. As was proper, the solution to the problem was first obtained in the laboratory. The

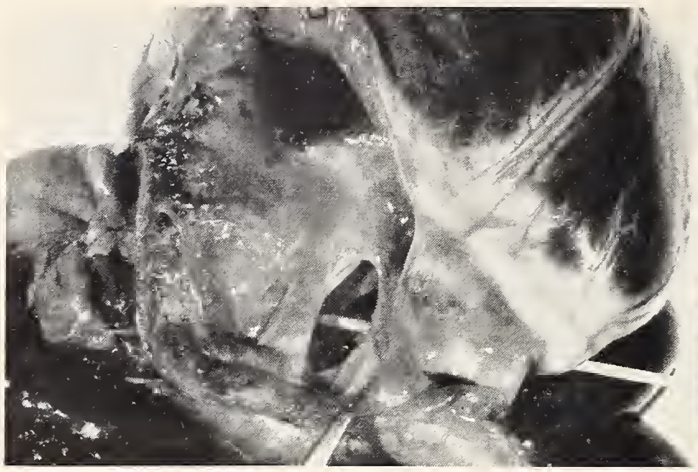

Fig. 1.

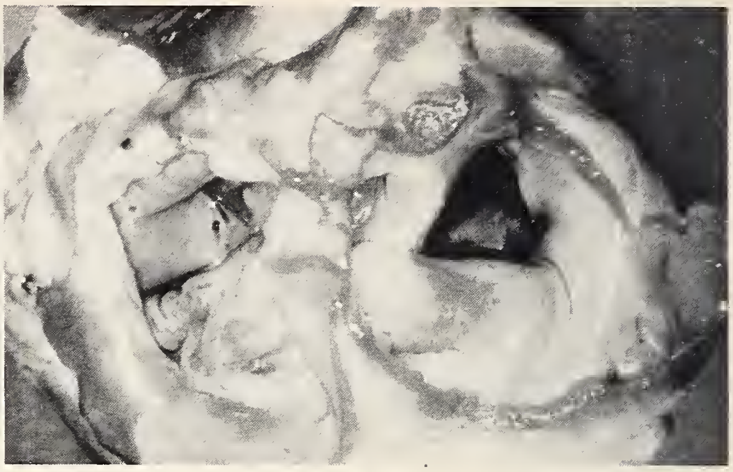

Fig. 2.

first report, in this regard, of real importance was that presented by Dr. Cohn[3] in 1947, wherein he described an extremely ingenious method for transplanting a segment of auricular wall, to the auricular septum, with the thought in mind that such a transplantation might be effective in closing auricular septal defects. Our study[13] began about this time with attempts to create large defects in the auricular septum. This was finally accomplished, after unsuccessful attempts with various closed methods, by the use of the temporary interruption of circulation, opening the right auricle and excising under direct vision the atrial septum. We placed an arbitrary time limit of ninety seconds as the upper safe limit for occlusion but by intermittently resuming and stopping circulation we were able to obtain four and one half minutes of operative time within the right auricle, which proved to be more than adequate to perform this job. Defects created experimentally in this fashion will remain patent and, in Figure 1 we see such a defect two weeks following its creation.

The first technique for closure which we tried involved what we have subsequently termed the principle of the "doughnut" auricle. This concept implied that it would be possible to invert a fair amount of tissue to the center of the septum, thus obliterating the central portion of the auricular lumen, yet at the same time allowing blood to flow around such tissue in such a fashion that adequate blood flow would be maintained. In the first experiments, the tips of the two auricles were inverted and sewn together through the septal defect (Fig. 2). This resulted in an 80 to 100 per cent closure of the size defects that we were dealing with in the experimental laboratory. In 1949 and 1950, this method was given clinical trial in a few patients. Although the patients tolerated the surgery, it was soon clear that we were not obtaining adequate closure of the large clinical defects found in these patients—defects many times larger than the experimental ones. Accordingly, we returned to the laboratory and devised a method for placing a plastic button across the septal defect.[14] The response of the heart to a polyethylene button placed in this fashion was quite interesting. The button becomes covered with fibrin in a few hours. Figure 3 shows a polyethylene button which has been in place within the auricle for twenty-four hours. One half of the button has been exposed in order to show the fibrin layer covering it. In the course of about three weeks this fibrin layer will be replaced by ingrowth of fibrous tissue from the periphery which becomes a smooth, glistening membrane (Fig. 4). The end situation of this technique then, is a plastic button within the lumen of the right auricle, occluding the interauricular septal defect, and held in place by the inverted tip of the left auricle to which it is sewn (Fig. 5). The left auricle is inverted only to maintain fixation, as we have always been concerned lest a foreign body placed within the heart might work its way loose and become migratory. This technique was also tried in a few patients, but here fixation of plastic buttons, adequate in size to occlude the very large septal defects which we encountered, proved to be difficult. At about this time, Bailey and his group[1] published the technique which they had developed, modifying the "doughnut" auricle concept, and utilizing auricle wall instead of appendage. Utilizing finger guidance, the wall of the auricle was sewn, with an interrupted suture, to the rim of the septal defect thus obliterating the lumen through the septum. Also, at about this

time, Gross[6] published his early experience with the use of the well, which allowed him to attempt to sew together at leisure, the rim of the septal defect, feeling with his finger and his instruments through the pool of blood in his well.

At this stage, then, there appeared to be two or three methods for the repair of interatrial septal defects, all of which suffered from the fact that they were performed blindly. At this time, also, in our laboratory, as in many other laboratories throughout the country, interest became focused upon the potentialities of hypothermia in the management of cardiac procedures. It appeared to us that of all intracardiac lesions, the interatrial septal defect was certainly one which should be most amenable to open visual repair. While we were studying methods in the laboratory to make it safer for human clinical application, the report of Drs. Lewis and Taufic,[8] from this great medical center in Minneapolis, of the first attempt which proved to be successful of the open closure of interauricular septal defect, was made. Since that time, we have adopted this method, and our last five patients have been operated with visual closure of their defect.

The application of hypothermia to cardiac surgery has already been throughly discussed. I wish merely to state that we cool our patients in a tub of ice water after they are under the effect of anesthesia. Constant temperature recording together with constant electrocardiograph monitoring is maintained. Experimentally, in the laboratory we found that hyperventilation was of great importance in reducing the incidence of ventricular fibrillation.[15] We found, moreover, that the use of potassium chloride was very helpful in resuscitative measures designed to defibrillate the ventricles in the event it should occur. Figure 6 shows segments of an electrocardiogram taken from an experimental animal undergoing hypothermia, who was made to fibrillate by the placement of a ventricular incision. Potassium chloride injected into the base of the aorta and massaged into the coronary circulation results in standstill which is then followed after cardiac massage by the resumption of rhythmic ventricular contractions. We felt, on the basis of our experimental observations, that it would be safe to attempt to explore the application of hypothermia to clinical surgery.

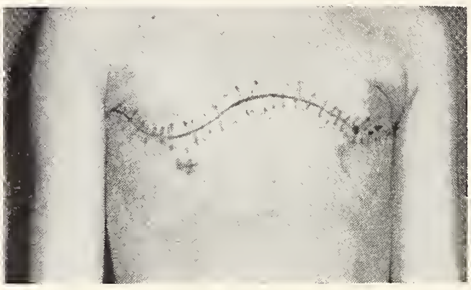

Fig. 7.

Interatrial septal defect was one of three lesions to which the method was applied. With your permission, I would like to describe some of the technical aspects of this procedure which we have found to be of value and importance. In the first patient with closure of atrial septal defect, we placed only a left anterior incision (Fig. 7). Exposure was not as adequate as we would have wished, and from this time on we have routinely placed the anterior bilateral sternum-splitting incision which we had previously used for pericardectomy and the removal of foreign bodies from the heart.[12] This incision gives maximum exposure of the heart and all its chambers, and allows one to manage any cardiac complication which might arise. Although long, this incision is a physiologic one, and, since no portion of the thoracic cage is removed, the patient is comfortable in the post-operative period and breathes well so that pulmonary complications are not common.

After the incision is placed, the first step is the ligation of the azygos vein, and the placement of tapes about the superior and inferior vena cava. The pericardium is now opened widely, and an incision into the auricle, well posterior, about an inch and one half in length, is made over a non-crushing clamp. Thus the incision into the auricle is made before circulatory arrest in order not to waste any of the valuable period of cessation of circulation.

Traction on the tapes around the vena cava is now made, shutting off the entrance of blood to the heart. After a few beats, allowing the heart to empty itself as much as possible, a clamp is placed across the base of the aorta and pulmonary artery. In addition, tourniquets previously placed about the root of the lungs are tightened in order to occlude the pulmonary veins. Thus, all vessels, entering or leaving the chambers of the heart, are occluded. The clamp on the auricular incision is now released, the residual blood in the heart is removed by suction and inspection of the chambers can be made. It is important not to forget to feel the mitral valve, through the septal defect, in order to be sure that this structure has not become involved as in the so-called Lutenbacher syndrome. The atrial septal defect may now be closed by sutures, using interrupted mattress sutures of silk. No matter how large the septal defect may be, in our limited experience, the edges will come together without tension when the heart is collapsed. We believe that when blood is allowed to flow again, the tension will not be increased sufficiently to cause tearout of the sutures. All of the sutures in the septum are placed and tied, with the exception of the last one. The line of closure is now held open by a forceps while the heart is flooded with saline solution forcing all air out of the left side. The final suture is now tied and cut under the surface of the water. More solution is poured in to fill the right side of the heart, and the non-crushing clamp is applied to the auricular incision. The various obstructing clamps to the lung roots, to the aorta and pulmonary artery are now removed, and the tape around the superior vena cava is released. Circulation at this moment is restored, at least partially. One observes the action of the heart and, as time goes by, the beat picks up and the myocardium becomes pinker, the tape around the inferior vena cava is finally released. Circulation is now totally restored. The incision into the auricle may be sutured, with interrupted sutures of silk, at leisure. Finally chest drains are placed in both pleural spaces and the incision is closed.

To date, we have operated on five patients using the open visual technique for closure of interauricular septum. In four of these patients, the operation was successful; the patients have done very well. In our opinion, these patients have complete closure of the septum. The fifth patient failed to survive the operation. He was a twelve-year-old boy who had a history of chronic heart failure, and was on digitalis for several months before operation. Although technically it was possible to suture the septal defect, his heart became distended and he died, in what we took to be heart failure, about two hours later in spite of resuscitative measures. The duration of total occlusion of circulation in these five patients varied from five minutes and fifty seconds to seven minutes and forty-five seconds. No suggestion of cerebral damage has occurred.

At the present time we feel that the safety of the open technique is sufficient to warrant further trial, inasmuch as the technical aspects of the closure of the septal defect is so much superior to any of the blind techniques, no matter how ingenious they may be.

Discussion

Dr. Ivan Baronofsky, Minneapolis, Minn.: It is indeed a pleasure to be asked to discuss "The Surgical Treatment of Interatrial Septal Defects." With all that you have seen and heard this afternoon with regard to the work of Dr. Swan, Dr. Bigelow, Dr. Crafoord, and Dr. Lewis, I feel very much like a discusser of a discusser. My experience in closure of interatrial septal defects is rather limited; however, my interest is great. In 1951 an attempt was made to close an interatrial septal defect in a youngster five years of age. This was done by an attempted inversion of the right atrial wall and then suturing the atrial wall to the rim of the interatrial septal defect. Catheterization studies of this youngster revealed partial closure of the septal defect.

I should rather like to present to you some interesting studies that were carried out by Dr. Carleton B. Chapman and Dr. Robert Fraser at the University of Minnesota Variety Club Heart Hospital.† Drs. Chapman and Fraser studied the hemodynamics of interatrial septal defects in nineteen patients. Clinical features of note are as follows: ages were from seventeen to fifty-one; ten were male and nine female; heart disease was detected early in life in three, in mid or late childhood (7 to 14 years) in seven; at the age of eighteen or later in eight; the chief complaints were shortness of breath in six, pain around the heart in five, palpitation in three, fainting episodes in one, and no complaint in two. Systolic murmurs were present in seventeen cases. Cardiac catheterization was accomplished in all of these cases. The oxygen content of blood samples taken from various sites and the femoral arterial saturation was determined (Table I).

The existence of functioning communication between the atria was thought probable if the oxygen content of the right atrial blood exceeded that of blood from the innominate vein or superior vena cava by 2.0 volumes per cent. Drs. Chapman and Fraser determined the systemic and pulmonary flows, mean pressure in the pulmonary artery and right ventricle, and right ventricular

SURGICAL TREATMENT OF PULMONARY STENOSIS

WILLIS J. POTTS, M.D.
Chicago, Illinois

IT is only eight years since Blalock opened the door to surgical alleviation of pulmonary stenosis. Intensive clinical study by the cardiologist has accentuated skill in diagnosis. Roentgenologists have learned the refinements of interpretation of cardiac silhouettes and lung densities. Through angiocardiography, knowledge of the chambers of the heart and its vessels is obtained. Cardiac catheterizations inform us concerning blood flow and interpret the significance of venous and arterial blood mixtures. The anesthesiologist has acquired skill in carrying these cyanotic patients through a long and arduous operation. Pathologists study our errors and stake out hazards along the course. Physiologists and pharmacologists continue to add to our basic knowledge of the heart, its action, its reserve, and its response to drugs.

Innumerable workers in many fields have done much for these children—the victims of cyanotic heart disease.

Our attitude at the moment towards the surgical treatment of the tetralogy of Fallot at The Children's Memorial Hospital, Chicago, is as follows:

If it has been demonstrated clinically that the child has infundibular stenosis with an interventricular septal defect, we approach the condition surgically by a posterolateral incision on the left side through the fourth interspace, provided the child is above approximately one year of age. If the arch is on the left, an aortic pulmonary anastomosis is done, making the opening 4 mms. in diameter, slightly less in very young children. If the arch curves to the right, a subclavian pulmonary anastomosis is done on the left through a similar incision. If the patient is an infant below one year of age and cannot live without surgical relief, an aortic pulmonary anastomosis is done on the right side.

In spite of all possible preoperative studies, it is at times impossible to be sure whether we are dealing with a tetralogy or a pure pulmonary stenosis. If the evidence leans towards tetralogy, a posterolateral incision is made and the pericardium is opened. If by palpation and observation, or pressure studies, the diagnosis is confirmed, a shunt operation is done. However, if the condition proves to be a pure pulmonary stenosis, a valvulotomy is done either in a retrograde fashion by way of the left pulmonary artery or the incision is extended and a transventricular valvolotomy is done.

Whenever a pure pulmonary stenosis is even suspected, a left submammary approach is chosen and, if the diagnosis is confirmed, a transventricular valvolotomy is done. If the patient is found to have an infundibular stenosis, the incision is extended laterally and a shunt operation is done.

What about the transventricular approach to infundibular stenosis as suggested by Brock? We have made a detailed post mortem study of forty-two hearts—some fresh and some in formalin-fixed condition. The results of this study will be published soon in the *American Heart Journal*. The photographs cannot be reproduced here, but it was concluded that about 19 per cent of the hearts had a type of infundibular stenosis which could well have been treated by intracardiac surgery. The fact that we found a smaller percentage amenable to simple intracardiac resection is probably due to the fact that the average age group in our series was far lower than that of other investigators. Eighty-two per cent of this series was comprised of hearts taken from children below three years of age, and obviously, represented the more severe types of tetralogy of Fallot.

Pulmonary stenosis with intact interventricular septum, more commonly labeled pure pulmonary stenosis, is most satisfactorily treated by transventricular valvolotomy as suggested by Sellors and Brock. The results of surgical treatment of this condition are truly spectacular.

A recent study of forty patients by Dr. Gibson at our hospital brings to light a number of interesting facts among which is the age factor. For some unknown reason, our patients have been much younger than those studied by other cardiologists. Nine were under the age of one year at the time of operation. Seven were between one and two years of age, eleven were between two

11 days to 3 years	15	8	53
3 to 16 years	5	0	0
	20	8	40

and five years, and the remaining thirteen were between five and fifteen years.

The surgical approach to these patients is as follows:

The chest is entered through the third interspace by a left submammary incision. The pericardium is opened. The use of novocaine in the pericardial sac and in the heart muscle has been discontinued. After placing a couple holding sutures in the wall of the right ventricle, the closed valvolotome is introduced into the right ventricular chamber, opened to appropriate size, thrust through the stenotic valve, closed and withdrawn from the heart. The expanding dilator is then introduced through the same opening and the stenotic pulmonary valve is dilated as widely as possible. The palpating finger on the pulmonary artery will be able to determine by the change in pressure and thrill that the pulmonary constriction has been properly opened.

If the patient, particularly a small child, is especially cyanotic and if its heart is greatly enlarged, holding ligatures are placed as above and the small knife valvolotome is quickly thrust through the constriction. The moment the stenosis is partially relieved the child's color changes and the heart action improves. It is then safer to proceed with the expanding valvolotome and dilator.

Mortality figures appear in Table I. It is at once obvious that when dealing with the tetralogy of Fallot, if the child's condition is such that it can survive to age three years, it has over 95 per cent chance of surviving surgery. Mortality must necessarily continue high in infants whose condition is so bad that immediate operation offers the only hope of life. Infants with tricuspid atresia do poorly after surgery. Results of a shunt operation in general are very satisfactory to the parents and the child but, of course, leave much to be desired from a medical standpoint.

The surgical mortality of pure pulmonary stenosis—one death in forty cases—is 2.5 per cent. The immediate and follow-up results of this operation are satisfactory to all.

Discussion

JOHN W. KIRKLIN, M.D. (Rochester, Minn.): It is an honor for me to open the discussion of the paper by Dr. Potts, who is a pioneer investigator and a brilliant surgeon in the field of congenital heart disease.

Tetralogy of Fallot.—The establishment of a shunt between the aorta, or one of its branches, and the pulmonary artery has been the treatment of choice for tetralogy of Fallot at the Mayo Clinic since its introduction by Blalock and its modification by Potts. In occasional cases of the tetralogy, however, for one or another reason, we have chosen instead to make a direct attack on the obstruction to pulmonary blood flow. This should not obscure the fact that at present we continue to employ the shunt operation in most of our cases. This situation may change when completely reliable means of working in the heart, in a bloodless field, are available to us.

It behooves us, then, to review the goals of the surgical treatment of patients with the tetralogy. The *ideal* goal would be a revamping of the intracardiac situation so that neither a right-to-left shunt nor obstruction to the flow of blood from the right ventricle to the pulmonary trunk would exist any longer. Until that anatomically ideal situation can be produced with a low operative mortality, we must be content with other goals. Symptomatic improvements, although real, are difficult to quantitate. We seek also certain physiologic changes as the means of producing the desired symptomatic improvement. These changes can be measured accurately. We seek to elevate the oxygen saturation of arterial blood during rest. We seek to prevent the profound fall in arterial oxygen saturation that characteristically occurs in these patients on exercise. Finally, we strive for reduction in the polycythemia as a response to these improvements.

In a high percentage of cases, the shunt operation produces these desired changes. For example in one case the oxygen saturation of arterial blood as determined by the ear oximeter was 76 per cent before operation and 91 per cent seven days after operation when the patient was at rest; it was 47 per cent during hard work (crying) before operation and 86 per cent seven days after operation. In the same case with the patient breathing 100 per cent oxygen the oxygen saturation of arterial blood was 78 per cent before operation and 86 per cent seven days after operation. In our opinion, any other operation besides the shunt operation which does not produce an anatomically normal heart must result in measurable physiologic changes comparable to those produced by a well-executed shunt in order to be considered equal or superior to aorticopulmonic anastomosis. Furthermore, the operation must be accomplished with the low mortality that now prevails for the shunt procedure.

Pulmonic Stenosis With Intact Ventricular Septum.—For cyanotic patients with pulmonic stenosis and intact ventricular septum, we seek an increase in arterial oxygen saturation and a decrease in right ventricular pressure as the result of operations. In cases of pulmonic stenosis with intact ventricular and atrial septa, we seek reduction in right ventricular pressure. Unfortunately, there is a paucity of information relating to the accomplishment of this reduction in pressure by the usual operation of pulmonic valvotomy as described by Dr. Potts. The information available suggests that although many patients improve considerably after the operation, some obtain only mild reduction of right ventricular pressure. This has stimulated some workers to a more radical attack on the pulmonic valve. Our experience with precise recordings of pressure changes at operation has suggested that such an attack will probably not succeed in bringing the right ventricular pressure to near normal in all cases. Our data indicate that in a significant percentage of cases of pulmonic stenosis with intact ventricular septum there is obstruction not only at the stenotic pulmonic valve but also in a narrowing in the outflow tract of the right ventricle.

Thus we have little enthusiasm for a more radical attack on the valve in such cases. Further improvement in the treatment of certain of these patients may be made by an additional attack, under direct vision, on the narrowed outflow tract of the right ventricle.

In closing these brief remarks, I should like to pay tribute to the fine address given by Dr. Potts and to thank this group for the privilege of opening the discussion on his paper.

IASD Interatrial septal defect.

pressure work. The following is a summary of nineteen cases (Table II).

A comparison was also made of the pressure work of the right ventricle in normal subjects and in patients with interatrial septal defects (Table III).

From the preceding information it would appear that patients with interatrial septal defects, with complaints that are referable to their heart, are indeed in incipient or actual trouble. It would appear that there is no question that surgical correction of this anomaly would be in order. The things that appear to hinder us in the surgical correction of interatrial septal defects are the following: (1) diagnosis of the presence of an atrioventricularis communis. (2) the ability to rule out anomalous pulmonary venous drainage into the right atrium, and (3) the ability to deal with bundle branch blocks which are common in interatrial septal defects.

I should like, lastly, to mention some personal communication that I have received from surgeons interested in this field. Dr. Robert Glover, of Philadelphia, writes that in five cases that he personally had operated on, the big problem that seemed to confront him was the presence of an atrioventricularis communis. In another two, the defect seemed to be extremely large with either no rim of tissue between the mitral and tricuspid valves or with such a tiny half-moon that any repair would prejudice normal valvular function. A fifth case was closed by a method of invaginating the right atrial wall against the defect. Dr. Charles P. Bailey writes that in twenty-four cases in which repair of the septum secundum was attempted, by his technique of atrio-septo-pexy, twenty-two were greatly improved. Postoperative catheterization has been done in ten patients. In all instances, the shunt was greatly reduced and in eight it was completely abolished. There were an additional fourteen cases of persistent ostium primum. The operative mortality in these cases was 57 per cent. All the survivors, however, have shown very definite clinical improvement. Dr. Robert E. Gross writes that he is still continuing to use the "Well" technique that he has published previously. His enthusiasm for this form of surgery continues very high, provided the individual has not yet passed into a state where there is a secondary change and increasing obstruction to the pulmonary vascular bed—which seems to him bad for any type of therapy.

REGIONAL ENTERITIS

Its Surgical Management

STANLEY R. MAXEINER, M.D.
Minneapolis, Minnesota

THE AUTHOR will attempt to define and evaluate five procedures used and recommended in the surgical management of regional ileitis, more properly regional enteritis, because any segment of bowel may be involved. Some go so far as to advocate that regional ileitis, certain granulomas and ulcerative colitis have the same or similar etiology. Neither etiology, symptoms, diagnosis nor medical management will be reviewed.

The five procedures listed below will be discussed: (1) conservation, (2) vagotomy, (3) ileocolostomy, (4) ileo-transverse-colostomy with exclusion, and (5) resection.

1. *Conservatism.*—An occasional laparotomy is performed under a mistaken diagnosis of acute appendicitis, or an acute ileitis is found unexpectedly. The bowel may be so acutely inflamed that radical surgery would create an unjustifiable hazard. It is generally agreed, under the circumstances, that the operation should be terminated at once, with or without removal of the appendix. Many believe that an appendectomy increases the risk or the likelihood of fistula formation, while others state that fistula results from the disease in the ileum and that the appendix should be removed. Repeated reports are available to establish the fact that some patients so treated improve on postoperative management and require no further surgery. Certainly, the finding of regional enteritis does not alone constitute adequate reason for radical surgery.

2. *Vagotomy.*—Vagotomy has been done for regional enteritis on the basis of favorable results following its use in ulcerative colitis. Thorek recently reported 80.9 per cent favorable results in twenty-one patients treated for idiopathic ulcerative colitis or regional enteritis by vagotomy. He preferred the transabdominal vagatomy because it gave opportunity to visualize the pathology. Graham states these results constitute additional evidence of the importance of psychosomatic factors in the etiology of the disease. One patient, twenty-four years of age, treated at our Veterans Hospital, in whom a laparotomy was terminated because of severe extensive inflammation, continued to have thirty to forty stools daily and his course continued unfavorable. This patient was treated by transthoracic vagotomy, but he obtained little improvement and one year later a laparotomy was repeated. The bowel showed marked improvement with two remaining skip areas and an abdominal vagotomy was performed. His course consisted of several remissions with numerous stools and malnutrition. Death ensued and autopsy examination revealed severe ileocolitis with ulceration and bleeding. A second patient extremely ill, treated by exclusion, ileo-transverse-colostomy and abdominal vagotomy, is doing fairly well with recurrence. In these cases, vagotomy has been of questionable value. It should probably be reserved for far advanced disease.

3. *Ileocolostomy.* — Ileocolostomy shunts the bowel stream by the diseased loops. It serves well as the first operation of a staged resection, necessitated either by the unfavorable condition of the patient or the far advanced state of the disease, or in the presence of fistula or abscess. As a definitive procedure, it has produced such poor results, that alone it should best be avoided.

4. *Ileo-Transverse-Colostomy with Exclusion.* —Ileo-transverse-colostomy, with exclusion, has produced very favorable results, especially in the presence of extensive bowel involvement, fistulae and/or abscesses. The small bowel is divided twenty-four inches proximal to the highest area of involvement, the proximal end is anastomosed to the transverse colon and the distal end turned in and dropped back. If partial obstruction is present in the lower segment and a blowout of the inverted end is likely, the distal end may be drawn out through a stab wound and a mucous fistula created. Ileo-transverse-colostomy with exclusion also serves well as a first stage before resection. As the disease subsides, the remaining

abscesses, fistulas, and diseased bowel may be removed with greater safety. Garlock reports the Mount Sinai mortality to be low with the exclusion procedure, and the results excellent. They (Bancroft) reported sixty-five cases treated by this method, with no operative deaths and only 13.8 per cent recurrence rate. Frobese states their experience confirms that of Garlock, and further, that they have had occasion to reoperate several of these cases and were surprised to find that all of the gross evidence of disease in the side-tracked loop had disappeared. In 1945 Garlock et al reported fifty-seven cases treated by this method without mortality, with six recurrences, an incidence of 10.5 per cent. However, in 1951, a subsequent follow-up showed an additional five recurrences among forty-seven cases, ten having been lost from observation, a recurrence rate of 23.4 per cent. He is convinced that exclusion surgery is followed by fewer recurrences than is resection.

Bockus, in discussing this paper, challenges Garlock's method of arriving at his percentages and states, "If we take the 103 cases of Dr. Garlock which have been followed up, forty-one are found to be either dead or have recurrences. To me, that means a bad result in approximately 40 per cent of the cases. If we review the entire group of 137 cases which he reported, we find that seventy-five of them are either dead or have recurrences or have not been followed up, which means 55 per cent have had bad or unknown results." Bockus further states: "Our group in Philadelphia happens to be the group (mentioned by Garlock) which has an authentic recurrence rate following operation (usually resection) which is well over 50 per cent in this entire group of diseases which includes regional enteritis and enterocolitis."

The experience of surgeons generally, is that the exclusion operation is of great value.

5. *Resection.*—Resection may be performed as a single stage with primary anastomosis or as a staged procedure after: (1) ileocolostomy, or (2) ileocolostomy with exclusion. Because the disease may start primarily in the bowel, resection has the great advantage of removing the involved segment and probably reducing absorption of toxins. On the other hand, the regional nodes are usually so extensively involved that complete removal of the disease is impossible. Still, exponents of resection contend that remaining disease often subsides or remains asymptomatic. Garlock's original statistics showed the mortality of resection (13.3 per cent) to be much higher than that for exclusion (0 per cent). With the accumulation of greater knowledge of the disease, better preoperative preparation of the patient, and the liberal use of antibiotics, we have had no surgical mortality in our own limited experience. At the Minneapolis Veterans Hospital the same experience has been obtained in the past three or four years since medical care was taken over by the University of Minnesota. Opinion in our locality definitely favors one-stage resection with primary anastomosis. Cattell states that from their experience a recurrence rate of 30 per cent may be expected. They prefer resection, and, with extensive involvement, perform staged operations. They have performed staged resections of diseased bowel too extensive to be safely done at one operation. Staging permits the patient to adjust his body metabolism without malnutrition. Six of his patients so treated have sixty inches or less of jejunum anastomosed to varying lengths of colon. Cattell has found, as have others, that resection of bowel without excising all of the grossly apparent disease, may be followed by relief of symptoms. Preoperative preparation is very important as malnutrition and the ravages of the disease may be corrected. Adequate quantities of blood, vitamins and food, together with suitable antibiotics (there is none specific), have greatly lessend mortality and morbidity. Equally important factors are the advances made in anesthesia and postoperative care.

Mortality and recurrences: Garlock early reported a mortality of 13.3 per cent after resection but none after exclusion with ileocolostomy. His recurrence rate was better in the latter. Several years later he states that in the exclusion operation, with no mortality, their over-all recurrence rate was 22.8 per cent. In cases treated by resection, their mortality rate was 14 per cent, with an over-all recurrence rate of 46 per cent. Cattell favors resection procedures, which they have done 160 times with only three deaths. They expect a recurrence rate of about thirty per cent. In a recent report from the Lahey Clinic by Kiefer, the last review of their statistics reveals a recurrence rate of 34 per cent. Recurrence has demanded reoperation as many as four times. Of forty-two patients who had recurrence, thirteen recovered without a second operation. Twenty-eight others were submitted to a second operation and eleven patients to a third operation and two to a fourth operation. These were desperate cases which taxed the skill of all concerned and in whom there was a salvage of twenty-seven patients.

Many physicians have repeatedly observed recurrences which have been almost asymptomatic, and which displayed a definite tendency to subside. We have at present one patient, who had a large segment of ileum and the large bowel to the mid transverse colon resected by the Lahey Mikulicz method ten years ago, who has a recurrence. He maintains his weight, carries on a gainful occupation, and plays golf and is being treated conservatively. Others who are known to have had incomplete removal of their lesions get along without great inconvenience.

Indications for surgery are not clear cut nor universally accepted by internists or surgeons. Certainly an x-ray diagnosis or an incidental finding of regional enteritis does not warrant radical surgery. Those who have had most experience with the disease and its treatment feel that surgery at present, when indicated, holds the greatest promise for relief. Both Garlock and Bockus indicate that their attitude toward treatment is, that they prefer not to operate until compelled to do so because surgery often proves to be only palliative. Indications for surgery of recurrent disease are similar to those for primary intervention. Garlock adds that all forms of treatment in a disease like ileitis, without known cause, must be empiric. Therefore, if surgery is palliative, their results must be considered extremely good. Frobese states that he is in agreement with the internists, namely, that only those cases deemed complicated or completely intractable to rigorous medical treatment, should come to operation.

Definitely, those patients who do not respond to medical treatment, who lose weight and bleed, or are unable to maintain a good state of nutrition, should be treated by operation. Similarly, those patients who develop abscesses and/or fistulas will require surgical treatment. Intestinal obstruction, either partial or complete, usually demands some type of surgical relief.

Summary

Although surgery offers the most successful method of treatment, it does entail a very definite mortality and a high rate of recurrence. It must be employed in carefully selected cases until the etiology of regional enteritis and better methods of treatment are discovered. For the present, surgery must be considered as palliative—certainly not curative.

HAZARDS OF THE AGED

Attention has been directed by press, radio, and television to the frightful toll of disaster deaths resulting from highway travel, airplane and train accidents, explosions, fires, and the like. . . .

It should not surprise us, therefore, to learn from the *Statistical Bulletin of the Metropolitan Life Insurance Company*† that accidents are a major threat to the life of the aged "outranking every other cause of death except the cardiovascular diseases and cancer. Of the 100,000 deaths from accidents in the United States annually, about 25,000 occur among people at ages sixty-five and over." These elderly people contribute one-fourth of all the victims of fatal accidental injury, although they comprise only 8 per cent of the total population. The death rate, says the *Bulletin*, in the above group is three times the rate at ages forty-five to sixty-four and seven times that at ages one to fourteen.

Three-fourths of all the fatal accidents among the elders were of two types, falls and motor vehicle injuries. Motor vehicle injuries were most prevalent for men and falls for women.

In terms of actual death rates, the total accident mortality among males was not far from twice that for females. Moreover, the toll from motor vehicle accidents was virtually three times as great for men as for women at ages sixty-five to seventy-four. The wide sex difference in the mortality from motor vehicle accidents reflects mainly the higher proportion of time spent by men on streets and highways. In each sex the majority of such fatalities were among pedestrians, indicating the difficulty that older people have in coping with modern traffic conditions. . . .

Accidents are much more amenable to control than any of the other major causes of death among the aged. The record for the past two decades shows that the mortality from accidents at the later ages has declined more rapidly than that from disease. Further progress could be made if elders learned to adjust their habits in accordance with their changing physical condition and if their environment, particularly in the home, were made as free from hazard as possible.

There is certainly a responsibility here stated and laid at the physician's doorstep. He can impress upon the elderly their limitations and upon their families the importance of eliminating all possible hazards in the home.—Editorial, *New York State Journal of Medicine*, February 1, 1954.

BOWEL OBSTRUCTIONS OCCURRING DURING THE POSTOPERATIVE PERIOD

LEO CULLIGAN, M.D.
Minneapolis, Minnesota

THERE is no field of surgery that is beset with more difficulties than is the differential diagnosis of the various types of bowel obstruction that occur during the postoperative period. Nowhere are the paths more uncharted. Often more than one condition is present, each accentuating the other. At times an accurate diagnosis is impossible; and, after exhausting every clinical and laboratory aid, one has to rely on his own intuition. In no other situation does "seeing the patient frequently" pay off so well, as it is often necessary to examine a patient many times before making up one's mind as to what is happening.

Diagnosis during the postoperative period is difficult because of several factors. First, we have a recent tender laparotomy wound. Second, there is always a normal postoperative ileus. Third, there are always normal chemical and electrolyte disturbances which have been initiated by the stress and shock of the operation. Fourth, there is a natural aversion on the part of the surgeon to re-open an abdomen which has just recently been explored. This is very justifiable in view of the high mortality associated with such procedure in the past. In 1950 Tito Korner reviewed 132 re-operations for various causes during the postoperative period of which 42 per cent were necessitated by intestinal obstruction. Of the 132 cases re-operated upon, 94 died, an over-all mortality of 70 per cent.

When confronted with a possible intestinal obstruction during the postoperative period, there are a few questions that are peculiarly pertinent to the problem, and if possible, we should always try to get satisfactory answers. First, is this a case of ileus, or is it a mechanical obstruction, Second, if there is a mechanical obstruction, is it simple or is it strangulated? Third, is the obstruction due to an inflammatory mass? The answers that we get to these questions will do much toward deciding whether or not it will be necessary to re-open the patient or whether conservative treatment is safer and will be adequate to relieve the situation. For if one re-operates an ileus, he adds fuel to the fire and usually makes his patient worse. If he re-operates a patient with an inflammatory mass and breaks through nature's barrier, he may cause a spreading peritonitis.

Any type of intestinal obstruction may occur during the postoperative period, and it is not my intent to cover the entire subject. What I am going to do is to outline five cases that presented some particularly difficult diagnostic problem during the postoperative period.

Case Reports

Case 1.—A man, sixty-five years of age, had been complaining of gas pains for about two weeks. X-rays were taken by the family physician and a constricting lesion, probably carcinoma of the transverse colon, was found. He was prepared for surgery. Neomycin was given for thirty-six hours prior to operation. He was operated on the 24th of September, 1952, at which time a contracted lesion of the transverse colon was found. On pathological examination this was found to be not a carcinoma, but a segmental area of ulceration approximately 3 cm. in length and extending completely around the bowel. His bowels moved normally on the fourth postoperative day, and he passed a moderate amount of stool and flatus following a small enema. On the sixth postoperative day, the patient complained of severe gas pains, developed abdominal distension, and a moderate amount of bloody serous drainage was noted on the dressings. Patient was x-rayed and large distended loops of small bowel were found. Cramping pains persisted for about three days, at which time patient began to have several loose stools and the cramps subsided. Patient went home on the twelfth postoperative day. The only plausible explanation for the x-ray findings and for the pains of which the patient complained from the sixth to ninth postoperative day was that when I examined him in the office I found that he had developed a moderate size ventral hernia. Apparently on the day that the bloody drainage appeared, a loop of small bowel had herniated into the wound causing a temporary complete obstruction. As this hernia enlarged, the obstruction relented and the mechanical obstruction was relieved. At no time was any bulging noted in wound while patient was lying in bed in the hospital.

Case 2.—A woman, aged forty, was first seen on the eighth postoperative day. She had been operated upon by a gynecologist for an ovarian cyst. There had been nothing unusual about the surgery except that during the course of removal of the cyst it had ruptured and a large amount of dark hemorrhagic material was released into the peritoneal cavity. Postoperative convalescence was normal until the fifth day, at which time she began to complain of gas pains and vomiting. These colicky pains

---

Presented before the Minnesota Academy of Medicine, February 11, 1953.

persisted for about three days getting progressively more intense and she began to have severe projectile vomiting. When examined, the patient had evidence of acute mechanical small bowel obstruction with active bowel sounds and distention. X-ray showed marked distention of upper jejunum. As soon as her fluids and electrolytes were replaced, the patient was operated upon. The point of interest in this case was the extremely firm plastic adhesions that started to cause obstruction signs on the fifth postoperative day. In the central portion of the small bowel it was completely and solidly agglutinated together for a distance of 2-3 feet. The bowel above and below this point was normal, making one feel that probably the fluid from the ruptured cysts had been extremely irritating and was the etiological factor in causing these firm plastic adhesions and resulting marked bowel obstruction.

Case 3.—This patient, a woman, aged seventy-five, I saw on her first postoperative day. A bad risk cardiac patient, she had been operated upon the previous day by another surgeon for a strangulated right femoral hernia. By the time the hernia sac was opened, the bowel had already slipped back into the peritoneal cavity and he was unable to inspect it. The next day he was worried about the condition of the bowel and asked me to follow the case along with him. Daily leukocyte and differential counts were obtained. The leukocytes remained persistently high, around 20,000. The abdominal distention and tenderness remained and there were distended loops of intestines seen by x-ray examination. In view of the x-ray and local findings and especially because of the persistent high leukocyte count, we decided to re-operate on the fourth postoperative day. A necrotic loop of bowel about 3 inches long was found friable, soft, and ready to rupture. This loop of bowel was resected, and an end-to-end anastomosis was carried out.

The recognition of a gangrenous loop of bowel inside the abdomen is probably one of the most difficult problems with which we have to deal. I think it is the recognition of this difficulty that has led the trend away from the conservative or non-operative treatment of mechanical obstruction. Rare is the surgeon who has not at one time or another missed a strangulated bowel—always to his regret.

The recognition of a strangulated loop of bowel has been based on criteria upon which there has been rather general agreement among surgeons. These are as follows:

1. Signs of peritoneal irritation
    (a) tenseness
    (b) muscle rigidity
    (c) rebound tenderness
2. Fever
3. Leukocytosis
4. Rapid pulse
5. Presence of mass

On the basis of these criteria, it was felt that one could be fairly certain of the presence of strangulation obstruction.

It is interesting and a bit disconcerting to read a recent article by Walter Becker. He made a study of 412 cases of acute adhesive obstruction attempting to determine whether the presence or absence of the above-named findings is sufficient to differentiate a strangulated from a simple obstruction. The results of his study showed the following: Leukocytosis was present in 50 per cent of the cases of strangulated obstruction and in 44.4 per cent of cases of simple obstruction. Of patients who died with strangulated obstruction, 60.8 per cent had a normal leukocyte count. Fever was present in 22.7 patients with strangulated obstruction, but also 16 per cent of patients with simple obstruction had a fever of 100 or more. Tachycardia with pulse of 100 was present in 22.8 per cent cases of strangulated obstruction but was also present in 14.8 per cent cases of simple obstruction. Tenderness and findings of peritoneal irritation were present in 81.8 per cent cases of strangulation obstruction but was also present in 72.2 per cent cases of simple obstruction. He did find, however, that it was only the occasional case that did not exhibit at least one of the "signs of strangulation." The conclusion reached was that the presence or absence of tenderness, fever, tachycardia, leukocytosis or palpable mass is not sufficient to differentiate simple from strangulation obstruction. He concluded that obstruction due to old adhesions should be surgically cared for as soon as blood volume, fluid and electrolyte balance are corrected. On the other hand obstruction due to recent adhesions should usually respond to suction treatment by gastrointestinal tube but he warned that conservative therapy must be used with great caution, and unless the evidence of recovery was unequivocal, an operation is in order. He showed that in cases where suction decompression has been abused, the mortality rate was 38.4 per cent. The moral to be learned is that regardless of the clinical and laboratory findings, a strangulated loop of bowel must al-

ways be considered as a possibility in any mechanical obstruction.

Case 4.—A woman, aged forty, mother of seven children, was first seen on her sixth postoperative day. She had been operated upon for an acute supperative but not ruptured appendix on November 10, 1951. Her postoperative course was characterized almost from the first by inability to alimentate. This started almost at once after surgery and persisted up to the time that I first saw her on the sixth postoperative day. During this period she had very little pain, had frequent emesis, numerous liquid bowel movements and had been passing flatus practically every day. When I saw her on the sixth postoperative day, she was listless, markedly distended, hiccoughing, and with rapid pulse. During her postoperative period she had been receiving about 2000 c.c. of fluid daily, half of this in saline and half in distilled water. Nasal suction was inserted on the third postoperative day. She did not tolerate it well, and it had been discontinued. She had a steadily falling urinary output from 900 c.c. on the third day to 100 c.c. on the seventh postoperative day. Radiographs taken on the sixth and eighth postoperative days showed what was interpreted by the roentgenologist on both occasions as being a mechanical, small bowel obstruction. Needless to say, this opinion worried us considerably.

A nasal suction was again inserted and approximately 2000 c.c. of gastric contents were aspirated. This gave the patient much relief, but distention of the small bowel persisted. Table I gives a résumé of her course until she was recovered on the twelfth day without further operative interference. The picture here was one of an acute distention of the stomach with ileus of small bowel. The loss of fluids and electrolytes resulted in a severe degree of hypokalemic alkalosis. Both the ileus and the alkalosis cleared after fluid and potassium loss were corrected.

Paralytic ileus is seen in pratically every postoperative laparatomy to some degree and as such is considered normal. When present to an excessive degree, it is due to a stimulation of an overactive sympathetic nervous system. Distententention interferes with normal absorptive action of the bowel, so that gas which normally would be absorbed tends to accumulate and aggravate the distention already started. The ileus here was accentuated by the hypokalemic alkalosis which was present to a marked degree.

Clinically ileus is characterized by marked distention of both the large and small bowel usually with a rapid onset soon after surgery. Intestinal colic is usually absent and there are no bowel sounds. The treatment of choice is a gastrointestinal tube, the best of which we have found to be either the Wild or the Grafton-Smith tube. Because either of these has only a single suction opening protected on the one side by the mercury sac and on the other by an air balloon, these tubes function better than the Miller-Abbott tube which has numerous openings. The use of potassium is beneficial in improving ileus. Often a patient will have a good movement as soon as he is given his first intravenous injection of potassium chloride.

Case 5.—This patient ran a similar clinical course, yet her pathologic history was entirely different. She was first seen on her ninth postoperative day. She was operated upon July 23, 1952, by a gynecologist for an unruptured ectopic pregnancy. Her left tube had been removed for a similar condition eight years previously, so at this time in addition to removing her right tube, a hysterectomy was performed. On her third postoperative day, she began to vomit and her abdomen became distended. Nasal suction was inserted, and she continued to lose from 1,400 to 3,000 c.c. daily by nasal suction. Her abdomen continued to be distended but every day she was passing small amounts of flatus. She had been receiving on the average 2000 c.c. of intravenous fluids daily, half of which had been in saline. Flat plate x-ray examination of the abdomen was taken on the eighth postopera-

tive day and was interpreted as follows: "Film of abdomen shows considerable distention of several segments of small bowel in the upper mid portion of abdomen, slight distention of the stomach, some gas throughout the colon. The appearance could be consistent with an ileus, however the possibility of a strangulation type of small bowel obstruction is to be considered." When I first saw this patient she was incoherent, restless, disoriented and moderately distended. Occasional gas sounds could be heard. The patient was very thin and presented a pot-belly type of distention in the lower abdomen. Table II gives a résumé of her clinical course and laboratory findings.

A radiograph taken on the fourteenth day showed a definite increase of gas in the colon. Presence of gas in the small bowel remained about the same, and the conclusion was a "partial mechanical obstruction not definitely excluded." The patient by this time had entirely recovered from her hypokalemic alkalosis. She was clear mentally, co-ordinated and alert. By this time I was convinced that she had a partial mechanical bowel obstruction. She was re-operated upon the fifteenth postoperative day. The small bowel was greatly distended to about 4 feet from the ileocecal valve. Gastrointestinal tube had stopped at that point. From there on to the cecum, the bowel was matted together by very firm adhesions agglutinating the bowel to itself and to the pelvis. The loops were separated and the obstruction relieved. Postoperative convalescence was normal.

If we have any reason to be happy about this case, it is the fact we postponed surgery until her potassium deficiency and alkalosis were corrected. Had she been reoperated during this phase, I am sure that a fatality would have ensued.

Discussion

These two cases illustrate how hypo-potassemia can readily develop in cases when one could expect a normal convalescence. One patient with an unruptured acute appendix and the other, with an unruptured ectopic pregnancy, had been receiving average amounts of parenteral fluid daily, but both were losing more electrolytes and fluids than they were receiving. Suddenly both were in marked toxemia from hypokalemic alkalosis. This is the most severe type of potassium deficiency. To produce this condition, three things are usually necessary: (1) inadequate intake of potassium; (2) loss of chlorides from the gastrointestinal tract, and (3) the increased secretion of adrenocorticotropic hormones resulting from the stress of surgery which hastens the rate of potassium excretion. When these three factors are present, there often results a profound illness with fever, anorexia and nausea, distention, muscular weakness, mental depression, confusion and delirium, irregular pulse and fall in blood pressure—the picture of hypokalemic alkalosis.

Abdominal distention which may be thought to be due to a neurogenic ileus may be due entirely to a potassium deficiency that may clear up quickly after the potassium deficiency is corrected. Also a delayed emptying of the stomach postoperatively may be cleared up quickly with the administration of potassium.

The body has no mechanism for storing potassium. Any excess of its normal needs is excreted in the urine. Any disturbance of the acid base balance—either alkalosis, which occurs when there is a loss of large amounts of gastric juice, or acidosis induced by losses of pancreatic, biliary or intestinal secretion will result in increased urinary excretion of potassium. Gastric juice contains the highest concentration of potassium of all the body secretions and may contain as much as 40 milliequivalents per litre which is two or three times the concentration of potassium in serum. In this way it is easy to see how continued vomiting or loss by nasal suction will rapidly induce a condition of potassium deficiency.

If a patient loses three or four litres of gastric juice daily, he will lose 80 to 100 milliequivalents of potassium, or approximately six to eight grams daily.

Cardiac disturbances are present frequently in potassium deficiency. Cardiac arrythmias, fall in diastolic blood pressure, and cardiac dilatation have been observed. Cardiac arrest during surgery has been noted in potassium deficiency. Wherever possible surgery should be postponed until potassium deficiency has been cleared.

Electrocardiograph findings are definite in character, but are a poor indicator of the exact potassium level. The changes that should be looked for are:

1. Decreased T wave voltage going on to a flattening or inversion of the T wave
2. Prolongation of the QT interval
3. Depression of the RST segment
4. Prolongation of the PR interval

Conversely, the development of a state of hyperpotassemia may be followed and diagnosed quickly by means of the electrocardiogram during rapid administration of potassium salt. Intravenous potassium can be given until the T wave becomes high peaked.

Since hypokalemic alkalosis in the surgical patient is most commonly produced by chloride loss together with potassium deficiency, the simplest rational treatment is the administration of potassium chloride. The chloride stays outside the cells and repairs the alkalosis, and the potassium moves inside the cell and helps repair the cellular potassium deficiency. This condition does not respond to sodium chloride and ammonium chloride if a co-existing potassium deficiency is present and is not cleared up. Hypokalemic alkalosis will rarely be seen if a surgical patient is managed by what is known as the "three-day rule." By this is meant that after three days of zero potassium intake, potassium should be provided by the mouth or vein.

Clinically, the administration of potassium chloride is usually followed by prompt clinical improvement. It takes on the average three days to restore serum potassium to normal, and it should be continued for another four days to prevent recurrence of potassium deficiency. Three grams or 40 milliequivalents, given intravenously with glucose, in distilled water or saline should be given three to five times daily depending on the needs of the patient. It must be administered very cautiously in a patient whose urinary output is low, as was the case of the fourth case I presented. Daily blood potasium levels should be obtained. Fluids containing potassium should be given slowly, no faster than 120 to 180 drops a minute.

Prophylactic use of potassium should be used on (1) patients who loose large amounts of gastrointestinal secretion by suction or fistula; (2) patients who receive only parenteral alimentation for a period longer than three days; (3) patients undergoing extensive surgery.

In all these patients, 2 litres each containing 2 grams of KCl should be given daily. In addition, another 3 grams should be given for each 1,000 cc. of gastro-intestinal fluids removed by suction or lost by fistula during a twenty-four-hour period.

In conclusion, I would like to emphasize that there is no place in the field of diagnosis where being wrong is so costly and where the rewards of being right pay off so handsomely as they do in the problems of intestinal obstruction that occur during the postoperative period.

DRUG THERAPY IN HYPERTENSION

A survey has been made of fifteen medical centers working on the problem of hypertension to assess the over-all opinion of the various drugs capable of specifically lowering the blood pressure. All fifteen centers had used hexamethonium, eight ergot derivatives, thirteen veratrum viride derivatives, and thirteen had used 1-hydrazinophthalazine. All fifteen observers reported administering the drugs to both hospitalized and ambulatory patients. Seven of the physicians thought that there was insufficient information to warrant widespread use of these drugs in the treatment of hypertensive patients at the present time. Two more advocated use of this type of therapy only in patients with malignant hypertension, and then only with proper precautions.—Moyer, J. H.: A survey on drug therapy in hypertension, Med. Records & Ann., 47:512 (May) 1953.

HYPERSPLENISM

HAROLD M. WEXLER, M.D.
Saint Paul, Minnesota

HYPERSPLENISM is an abnormally increased activity in one or more of the spleen's functions. It manifests itself by diminishing the numbers of one or more of the three cell types of the blood. The condition may be inherited (familial hemolytic anemia); it may arise out of a primary blood dyscrasia, a generalized infection, or metastatic neoplasm to the spleen. Spontaneous cases are frequent in that hypersplenic episodes occur which are unrelated to any known cause. Any instance in which the spleen enlarges may cause hypersplenism. It is important, however, to differentiate between splenomegaly and hypersplenism—the former being only an anatomical term, the latter being functional. A normal pregnancy or insignificant trauma or minor infections may precipitate severe exacerbations in vulnerable individuals.[21]

Pathogenesis

To better understand the pathogenesis of this syndrome we must look at the anatomy of the spleen. The capsule is made up mainly of smooth muscle fibers which penetrate to the depths of the organ. This enables a marked contraction of the spleen with exercise, massive bleeding, anger or the injection of adrenaline.[18,21] The spleen in a relaxed living body is three to five times heavier than the spleen at autopsy, for there is marked contraction of the organ at death's door. The blood courses slowly through the splenic pulp (so slowly at times that the blood does not appear to be moving) and finally ends in the venous sinuses.[18] Throughout its course the individual cell (be it erythrocyte, leukocyte or platelet) must stand a rigid inspection for countless reticulo-endothelial cells lining the vascular channels. And woe be it for the damaged or senile cell, for there is a selective phagocytic action by the reticulo-endothelial cells on the defective cell. It is immediately apparent that the spleen can influence levels of the blood elements by vascular storage and phagocytosis. In addition, the spleen has been estimated to contain one fourth to one third of the lymphoid and endothelial tissues of the body and these cells are thought to be one of the chief producers of antibodies in various immunological defense mechanisms.[21,27] Up to this point there is rather complete agreement among hematologists. Unfortunately, however, most of these men go their separate ways in considering the pathogenesis of the syndrome. A few feel that a perverted storage and phagocytic function is the cause of hypersplenism;[8,9,10] more men think that abnormal humoral factors causing a suppressive effect on the bone marrow and destructive effect in the peripheral circulation is the cause;[7,11,14,25] recently most hematologists are of the opinion that there is probably a combination of these factors in the production of hypersplenism.[12,18,22,24,27]

It is interesting to note that the normal spleen can be removed with impunity, leaving no evident disability.[8,22] On the other hand, a splenectomy in certain hypersplenic states is mandatory to preserve the life of the patient. Here then, we have a true medical paradox, an organ for which the body has no apparent need when normal but with severe and even death-dealing effects when perverted.

Diagnosis

The history is important in the diagnosis of hypersplenism but since it varies with the different syndromes it will be dealt with later. A constant physical finding is splenomegaly. If one cannot palpate the spleen but there is a great suspicion of hypersplenism, it would be well to get a scout film of the abdomen to determine the size of the spleen since one has great difficulty in palpating the spleen until it weighs 500 grams. The one notable exception to splenomegaly in this condition is idiopathic thrombocytopenic purpura, and although the spleen is not clinically enlarged, the organ at the time of surgery frequently weighs two to three times the normal spleen (approximately 150 grams). A peripheral cytopenia is present, the cell type or types affected varying with the syndrome with which one is confronted. The bone marrow invariably shows compensatory hyperplasia of those cells which are deficient in the blood. Whether there is normal maturation or

---

Dr. Wexler is a medical fellow, Veterans Administration Hospital, Minneapolis, and Ancker Hospital, Saint Paul.

maturation arrest varies according to the prejudices of different authors and the technical skill of the man looking at the bone marrow smear. The adrenaline test is a subject of much controversy among hematologists, and here again, opinion is equally divided as to the value of the test. If, after injecting enough adrenaline to cause an increase in the pulse rate (usually 0.5 to 1.0 cc. 1:1000 solution), one finds an increase in the cellular elements which are deficient in the particular syndrome one is dealing with, the proponents of the test claim that this is proof of splenic hypersequestration.[8,9,10,26] The opponents[7,24] of the test counter by saying that approximately 50 per cent of patients who have unquestioned hypersplenism will not have a significant rise in the depleted cells; moreover, many patients who have long had their spleen removed surgically will have a positive test. It should be said that the adrenaline test is frequently used in the diagnostic work-up of a suspected case of hypersplenism, and when positive it indicates, but does not necessarily prove, splenic hyperactivity. Various tests Coombs, trypsinized red blood cells, Weiner's, et cetera) which demonstrate incomplete antibodies, either in the patient's serum or adsorbed on the patient's red blood cells, are helpful confirmatory tests. It is important to realize that although the test was originally devised to detect acquired hemolytic anemias, a small but significant number of positive titres are obtained in many other hypersplenic syndromes which do not have a hemolytic component. The titres obtained in tests demonstrating univalent antibodies do not appear to be correlated with the activity of the disease.[25] Splenic puncture has been advocated recently by Calkins[4] not for making a diagnosis of primary hypersplenism (a very difficult if not impossible pathological diagnosis) but for finding the cause of acquired hypersplenism seen in conditions such as obscure malignant lymphomas, infections and certain metabolic disturbances or for ruling out cases of myeloid metaplasia. The only contraindications to splenic puncture are a platelet count less than 50,000 or impaired bleeding, clotting, and prothrombin time. Sixty cases were biopsied without event. One merely infiltrates with novacaine down to the spleen and, with a 20-gauge needle and a 5 cc. syringe, aspirate a small amount while the patient is in deep inspiration.

TABLE I. DIFFERENTIAL DIAGNOSIS OF PRIMARY AND SECONDARY THROMBOCYTOPENIAS

	Etiology	Familial	Splenomegaly	Sex	Age	Lymphadenopathy
Primary H., T.	?	occ.	0	F 2:1	young	0
Secondary H., T.	Hypersensitivity to chemicals, vegetables, animal products, physical agents, blood dyscrasias, anemias, infections, any disease associated with splenomegaly	0	present	both	any	occ.

Classification

The following is a list of hypersplenic syndromes which are well recognized:

(a) Primary hypersplenism, thrombocytopenic (idiopathic thrombocytopenic purpura or Werlhof's disease).
(b) Secondary hypersplenism, thrombocytopenic (acquired or secondary thrombocytopenic purpura).
(c) Primary hypersplenism, hemolytic (familial hemolytic anemia).
(d) Secondary hypersplenism, hemolytic (acquired hemolytic anemia).
(e) Primary hypersplenism, neutropenic.
(f) Secondary hypersplenism, neutropenic.
(g) Primary hypersplenism, pancytopenic.
(h) Secondary hypersplenism, pancytopenic.

It is beyond the scope of this paper to describe in detail the above listed syndromes; however, the salient features and the differential diagnoses will be discussed. It should also be emphasized that one rarely sees a "pure" neutropenia, a "pure" thrombocytopenia or a "pure" anemia.[8] Although the predominant syndrome may be hemolytic anemia, for instance, if one looks carefully enough there will usually be a cytopenia in one or more of the other cell types. Curiously enough a hypersplenic syndrome with a diminution in one cell type may completely reverse itself—the previously diminished cell type will come back to normal, only to have a precipitous drop in one or both of the other cellular elements. This phenomenon occurs occasionally after splenectomy.[8]

Thrombocytopenic Syndrome

The thrombocytopenic syndrome is characterized by spontaneous bleeding anywhere in the

TABLE II. DIFFERENTIAL DIAGNOSIS OF PRIMARY AND SECONDARY HEMOLYTIC ANEMIAS

	Etiology	Familial	Coomb's	Age	Results from Splenectomy
Primary H., H	?	always	pos. 32%	children	98% cures
Secondary H., H.	Chemicals, infections, carcinoma, leukemia, lymphomas, any condition asso. with splenomegaly	0	pos. 83%	Adults	30-40% cures

body. The onset and course are variable. Typical laboratory data are: low platelet count; increased bleeding time; positive cuff test; no, or poor, clot retraction; decreased prothrombin consumption (increased prothrombin conversion time).[19] Occasionally one may find an anemia secondary to the bleeding. Bone marrow shows adequate numbers of megakaryocytes, but platelet production is greatly diminished according to most authors.

In treating the primary or idiopathic thrombocytopenias, age is an important factor. In an adult, surgery is considered to be an emergency procedure in some clinics because of imminent cerebral hemorrhage.[7,8] In children, a period of observation for three to six months is indicated if hemorrhage is not severe, for several cases of spontaneous recovery have been reported.[1] One is also more prone to do surgery on females early because of massive bleeding during menses, and more frequent and severe recurrences in females. Those cases which have bone marrow eosinophilia and good response to ACTH or cortisone are considered to have a favorable prognosis. Therapy, preoperatively, is blood transfusions if indicated, cortisone, and recently, plaelet-rich polycythemic blood with siliconized apparatus has been advocated.[19]

In treating the secondary thrombocytopenias, it is mandatory to find the cause of the underlying or primary disease process and treat that if possible (i.e. in lymphatic leukemia irradiate the spleen). Blood transfusions and ACTH are used in some cases. If treatment of the primary disease is not possible and the bleeding is a threat to the patient's life, surgery is necessary. The mere fact that surgery does not affect a cure in every case, and that the disease is self limited in certain cases, mean that there are other factors we know nothing about in this disease. Five year "cures" for the primary form are 70 per cent, for the secondary form 54 per cent.[19] Approximately one third of the failures became cures after re-exploration revealed accessory spleens. It is sometimes useful to inject thorotrast for visualization of aberrant splenic tissue.

Hemolytic Syndrome

The hemolytic syndrome is characterized by weakness and jaundice with no characteristic onset or course. Splenomegaly is invariably found on physical or roentgenologic examination. A normocytic, normochromic anemia, bilirubinemia, reticulocytosis, increased fecal and urine urobilinogen, spherocytosis, increased fragility of red blood cells and erythroid hyperplasia of the bone marrow are present. It should be stressed that anemia develops only if the destructive process in the peripheral circulation is greater than the regenerative process in the bone marrow. To illustrate this point, many hemolytic anemias have M-E layers of 50 to 80 per cent in contrast to the 5 to 8 per cent M-E layer in the normal marrow.

In the primary hemolytic syndrome (familial hemolytic anemia) surgery provides the best results (cures obtained in over 98 per cent of cases; misdiagnosis is thought to be the reason for the 2 per cent failures). However, since many cases are found accidentally late in life without any manifestations of severe anemia, one should not suggest splenectomy indiscriminately. Surgery should be reserved for children, young adults or severe hemolytic anemias in the older age group.[5,17] In secondary hypersplenism, hemolytic (acquired hemolytic anemia) results from surgery are much less favorable and every effort should be made to treat the underlying disorder before one resorts to surgery. Whether it be the primary or secondary hemolytic syndrome, blood transfusions are to be avoided during hemolytic crises and before surgery.[8,9,10] In addition, surgery should be delayed until a hemolytic crisis has passed.

Neutropenic Syndrome

In the neutropenic syndrome one is usually confronted with an insidious onset of malaise and tendency to repeated infections which are difficult to clear. The course is usually chronic although numerous fulminating cases have been reported. The physical examination will usually demonstrate one or more foci of infection. Splenomegaly, neutropenia, and normal or granulocytic hyperplasia of the bone marrow (with or without maturation arrest) are invariably present. There may or may not be an absolute decrease in the lymphocytes. The fact that one usually sees old segmented granulocytes and an absence of young neutrophils favors the hormonal theory in the pathogenesis of this syndrome.[27] One has difficulty in differentiating the primary and secondary forms of neutropenia unless there is an obvious underlying disorder of the spleen. If one fails to find the etiology, splenectomy is the therapy of choice. In the primary neutropenias surgery affords an 85 to 90 per cent cure rate. In secondary hypersplenism, neutropenia, surgery will lead to cures in 60 per cent of the patients. Prior to and immediate after surgery antibiotic therapy is indicated prophylactically even if no focus of infection is present.

Pancytopenic Syndrome

The pancytopenic syndrome is so variable in either the primary or secondary form that no attempt will be made to describe it. Suffice to say that at some time in the course of the disease, symptoms referable to the depletion of one or more cellular elements of the blood will manifest themselves. One may have only a thrombocytopenia for a time. This may correct itself spontaneously only to have a hemolytic crisis or a neutropenia or possibly a combination of all three processes. Again, if one can find and treat an underlying disorder of the spleen, one should do so, but more frequently this is not possible. Splenectomy gives good results in a majority of cases but late recurrences (up to five years) are not infrequent. The acute hemoclastic crisis in hypersplenism may present itself as hemorrhage, hemolytic anemia, sudden sepsis either alone or in combination with one another. Most speculation has been confined to the onset of hemolytic crisis in primary hypersplenism, hemolytic (familial hemolytic anemia).[21] Dameshek and Bloom feel that this is due not only to excessive peripheral destruction of red blood cells, but also due to a maturation arrest of the erythroid series in the bone marrow. Owren believes that crisis arises from a temporary aplasia of the bone marrow (from infection, toxins, et cetera) and the reticulocytosis seen is actually the recovery phase in which the bone marrow is attempting to compensate for a previously diminished production of red blood cells. Doan and Wiseman think that excessive destruction in the spleen could explain the crisis. Troland and Lee have demonstrated a precipitous drop in platelets with purpura when splenic extracts from a case of idiopathic thrombocytopenic purpura were injected into experimental animals. Harrington also demonstrated a precipitous platelet drop in normal persons when serum from cases of idiopathic thrombocytopenic purpura were injected[15].

The term "relative hypersplenism" has been coined to explain those cases of cytopenia from permanent bone marrow damage (toxins, drugs, heavy metals) where cellular recompensation has occurred with the splenectomy. The postulated mechanism is that the spleen had not decreased its normal destructive effect to balance an impaired bone marrow cellular production. Whatever the case might be, splenectomy with hypoplastic bone marrows has definitely alleviated hematological symptoms in several well-documented instances.[5,22,27]

Within a few hours after removal of the spleen, the neutrophils rise (as in any surgical procedure).[1] At one week there is another peak in splenic neutropenia and thereafter there is a gradual diminution to normal or slightly elevated levels. Several months postoperative there is an absolute lymphocytosis with only a relative granulopenia. Four days usually elapse before platelets attain normal blood levels and another eight days pass before maximum levels are reached. Platelet counts have been recorded as high as four million.[1] Postoperative thrombotic phenomena are quite rare, however. If the platelet count is greater than one million, prophylactic anticoagulants are employed.[1,4] The platelet count gradually diminishes to normal levels. Although it ordinarily takes four days for the platelet count to become normal there are case reports in Werlhof's disease in crisis that impresses one with the variability of response or that other unexplained factors play a major role in the spontaneous bleeding. Within minutes after clamping the splenic pedicle there is a seemingly miraculous cessation of oozing in the skin surfaces and subcutaneous tissues.[1] It is also interesting to note that in some cases, although the platelet count remains down in the spontaneous bleeding range of less than 50,000, all bleeding tendencies subside.[19] Conversely, there are cases where the platelet count rises to normal, yet spontaneous bleeding continues to occur.[5] The red blood count and hemoglobin rise slowly after a splenectomy reaching, or approaching, normal values only after two to four weeks have elapsed.[27] In the post-splenectomy state, one regularly notes Howell-Jolly bodies, reticulocytosis, normoblastosis, and target cells, which, because of their flattened form, are more resistant to hypotonic saline.

Although much knowledge has been gained from splenectomy the response is so variable that we are still unable to ascertain whether the activity of the spleen is primarily destruction of cells or inhibition of the bone marrow.[5,27] Regardless of this problem, we are still faced with the fact that the spleen *per se* is not the only regulator of the cellular elements of the blood—it is more likely that the entire reticulo-endothelial system takes part in this syndrome of "hypersplenism" and for this reason, many of the leading hematologists would rather substitute the term "hyper-reticulo endotheliosis."[17,24] Kracke has aptly summarized the proper approach to a suspected case of hypersplenism.[18]

(1) Is the spleen destroying cells more rapidly than the bone marrow is capable of producing?

(2) Is the bone marrow capable of producing a normal number of cells?

If the answer is yes to both questions, then one must decide whether it is safer to leave the spleen in or to risk surgery (1 to 5 per cent mortality rate) in removing the spleen.

TREATMENT IN CONGESTIVE HEART FAILURE

The clinical signs and symptoms of congestive heart failure result from two causes. There are symptoms caused by altered pressure-flow relationships in the cardiovascular system, and there are symptoms resulting from abnormal fluid and electrolyte metabolism, affected by several mechanisms. Therefore, therapy should be directed toward restoring a better balance between cardiac output and metabolic requirements, promotion of sodium and fluid loss, and maintenance of the equilibrium between the intake and excretion of salt.—Hanenson, I. B., et al: Pathogenesis and treatment of congestive heart failure. M. Clin. North America, 37: 643 (May) 1953.

Case Report

ARSENIC POISONING RESULTING FROM TREATMENT OF CARDIAC ASTHMA IN AN ALLERGIC PATIENT

J. S. BLUMENTHAL, M.D., F.A.C.P.
Minneapolis, Minnesota

A male paper maker, aged fifty-two, was hospitalized for severe generalized abdominal cramp-like pains, weakness, frequent vomiting and diarrhea, and an itching skin rash and asthma. These symptoms, but for the asthma and skin rash, were of twelve days' duration with a gradual onset. The pain had no relation to meals, exertion or any known factor. The diarrhea was profuse, watery, occurring four to five times daily irrespective of food eaten and was resistant to routine therapy including antibiotics.

The patient is married and has one child. The history of asthma dates back fifteen years. The symptoms first had occurred only in spring and fall and were associated with a stuffy nose. Gradually, these symptoms had become perennial and were aggravated bv dust, paint, sea food, dairy products, alcohol, cooking odors, and severe emotional episodes. He had an allergic work-up twelve years ago, but had little difficulty when he stayed away from known etiologic factors. In July, 1952, he had a "cold" with slight fever, weakness, chest pain, and cough for which he was hospitalized for two weeks and from which he did not seem to recover. Since then his "asthma" has become much worse so that he wheezed a great deal and could not work, as any exertion aggravated his wheezing.

In September, 1952, he went to an allergist who gave him skin tests and told him to stay on a new elimination regime of contactants, foods, and inhalants. He was also given injections for desenitization, but there was no improvement of note. He then was told by a friend, to go to a clinic in Mississippi where he rested and was placed on medication with some relief of his asthma, but on his return home there developed a gradual and increasing onset of his present complaints. The past history is not remarkable, except for a skin rash on the lower extremities which occurred on excessive use of soap or wool; and hives with the use of sulpha drugs three years ago. There is a history of known high blood pressure for five years, but with no referrable symptoms.

The patient was orthopneic when I first saw him in consultation on February 18, 1953, and in evident distress. He was wheezing, coughing, and a little hoarse, and expectorating a stringy thick sputum. There was puffiness about the eyelids and face, 1 plus edema of the ankles and increased pigmentation in the axillae. There was scaling in these areas as well as on the lower extremities with some keratosis of the palms and soles. The conjunctivae were congested. The nasal membranes were boggy and pale with a bluish tinge. The heart was markedly enlarged to the left with A_2 greater than P_2. Its rate was regular with a systolic murmur at the base. Wheezy, inspiratory and expiratory rales were heard in both bases. The blood pressure was 170/110. The abdomen was soft with tenderness in the right upper quadrant. The liver margin was down 4 cm.

Because of these findings and the history of medication for asthma at the clinic in Mississippi, the diagnoses entertained were (1) arsenic poisoning with hepatitis, gastroenteritis, dermatitis, melanosis, (2) cardiac decompensation, (3) allergic asthma and rhinitis, (4) hypertension heart disease, and (5) coronary disease.

The laboratory findings of interest were: a trace of albumin-uria, stools negative, x-ray flat plate of the abdomen, barium meal, and barium enema studies were negative. Blood cholesterol, and prothrombin time were normal. Thymol turbidity was 6.80. Sulphabromophthalein sodium test revealed 10 per cent retention in one hour. The cephalin cholesterol test was 2 plus. The electrocardiogram had a flat T_1 and ventricular extra systoles (Figs. 1 and 2). Chest plates taken February 19, 1953, showed a heart measuring 18.1 cm. or 60.3 per cent of the total thoracic width of 30 cm. with bilateral pleural effusion. Nails and hair and urine were submitted for analysis for arsenic with the following findings:

Report on chemical analysis of samples of nails, hair and urine in case of A. P. submitted on February 24 and 25, 1953.

Laboratory report—The nails contained 2358 milligrams of arsenic calculated as Arsenic Trioxide per 100 grams of nails. This is equal to 2.358 per cent of Arsenic Trioxide in the nails.

Laboratory report—The hair contained 0.55 milligrams of Arsenic calculated as Arsenic Trioxide per 100 grams of hair.

Laboratory report—The urine contained 0.10 milligrams of arsenic calculated as Arsenic Trioxide per 100 ml. of urine.

The patient was digitalized and put on a salt-free diet with dramatic and prompt improvement in his orthopnea, ankle edema and asthma and more gradual but persistent alleviation of other symptoms. No B.A.L.[1] was used. A 6-foot radiograph of the heart taken on February 25, 1953, showed a heart 15.3 cm. in diameter or 51 per cent of total thoracic width and on March 10, 1953, it was 14.2 cm. or 47.3 per cent.

Here, then, we have a patient who is allergic and developed cardiac decompensation. Further, indiscriminate, unsupervised treatment with arsenic complicated the picture. At the clinic in Biloxi, Mississippi, he stayed five days and then was told to go home. He was given Doxychol X for six months—one tablet p.c. and Dicalossa three times daily for twelve months. Most important, however, is the red liquid which he was told to take three times daily until all cleared up, "probably six weeks," after which it was to be reduced to twice daily for six months and then once daily for eighteen months. If, however, the symptoms recurred, the dose was again three times a day until clear of asthma and two weeks longer.

The patient was advised that any prescription given by the family doctor may be taken at the same time with no hesitation. Further, in upper respiratory infections,

Read before Minnesota Society of Internal Medicine at University of Minnesota, Minneapolis, May 23, 1953.

they (I quote from the clinic literature) "have found chloromycetin particularly helpful since it is a synthetic antibiotic and has no adverse reactions of consequence." They "strongly" advise that this red medicine must not be discontinued and that an occasional skin eruption or moderate swelling is not dangerous and may be reported, but no reduction should be made in dosage. In order to keep adequate supervision, they state "you must write to us for more medicine (usually four to six bottles) and it is essential that you give us the following information so that we may make a change in your formula if it seems advisable to do so:

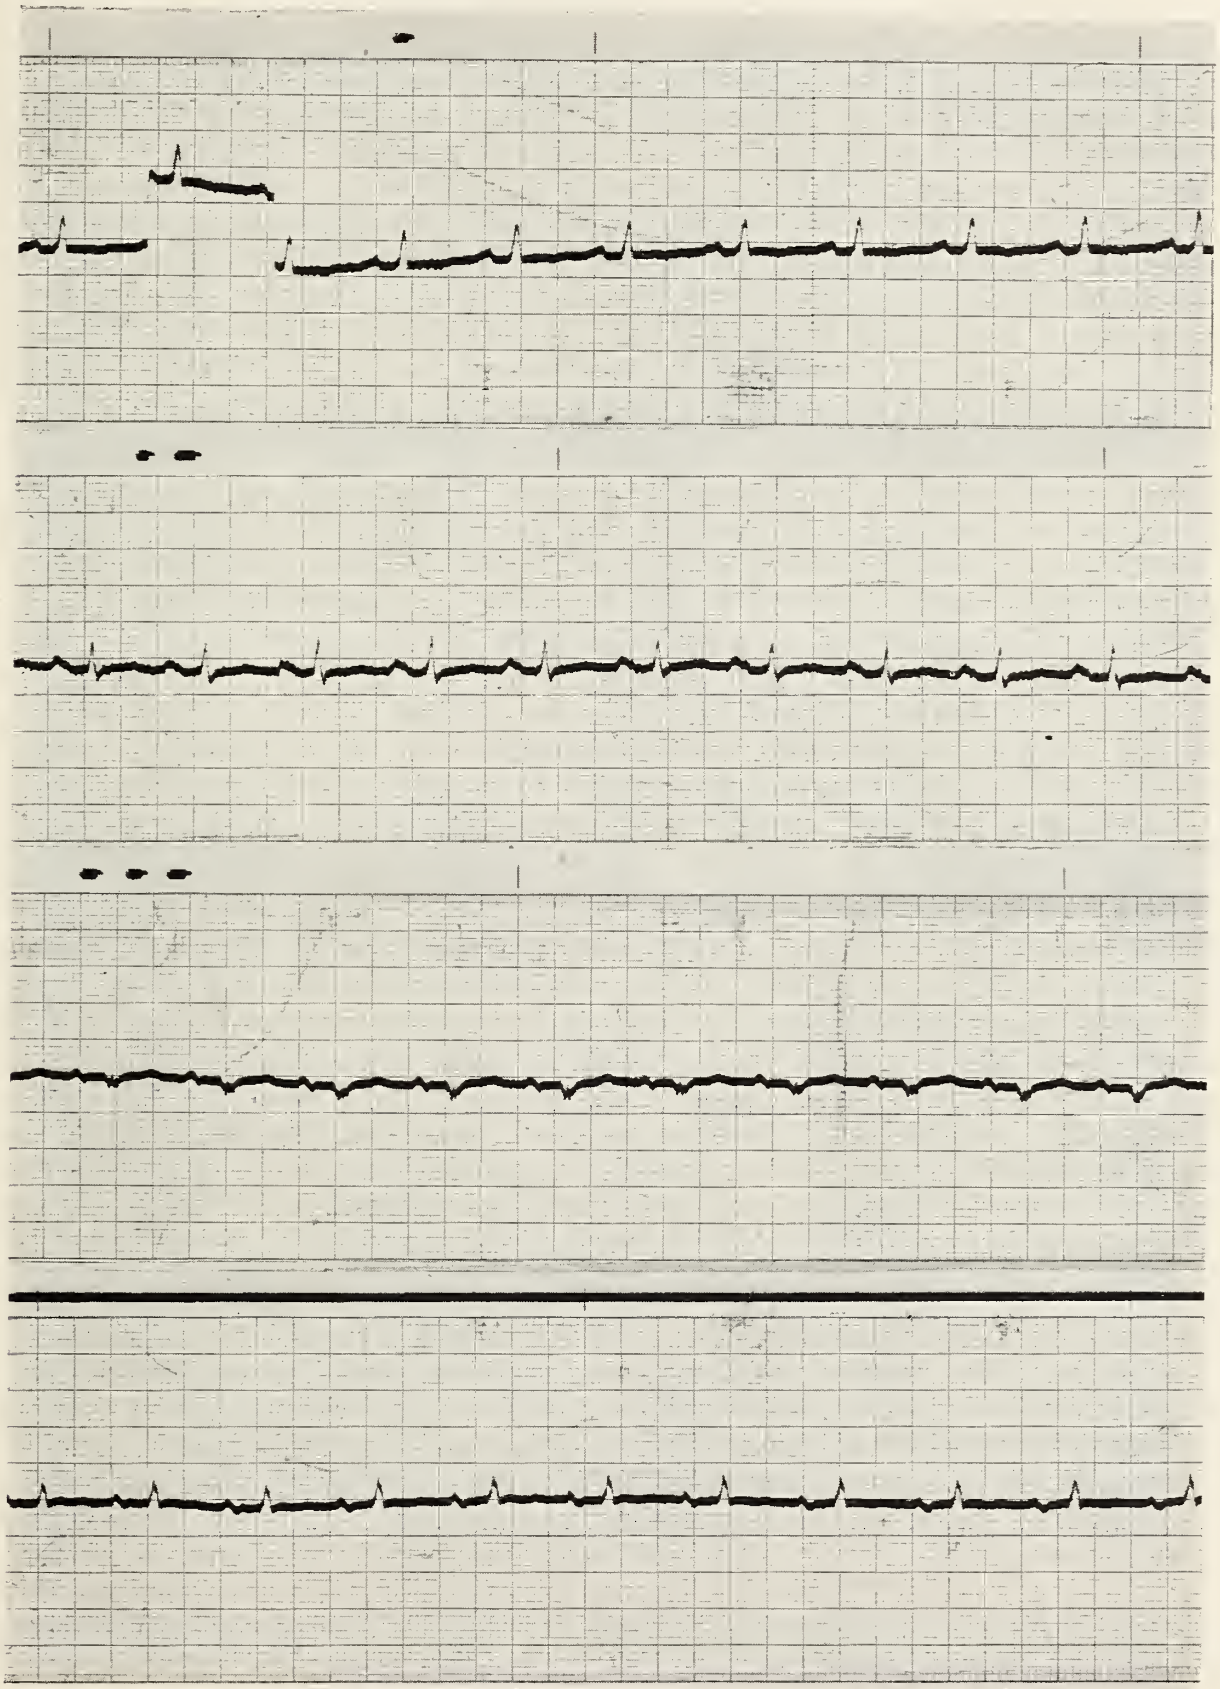

Fig. 1.

1. How often are you taking red liquid medicine?
2. Are you having any asthmatic attacks as evidenced by wheezing, excessive coughing or a 'tight chest'?
3. Are you having any other allergic manifestations, i.e., hay fever, eczema, hives?

4. Are you getting along better since on this treatment? If not, tell us the details.
5. State your weight (if known) and let us know about bowel regularity, conditions of skin, appetite, fever if present, swelling, sleep, and emotional upsets."

They assure the patient that the red coloring matter is an inert substance approved by the Federal Food and Drug Administration and the fading of color does not affect the efficiency of the medicine. Nothing of what the solvent really contains is mentioned. They refill the medicine for $2.50 per bottle postpaid.

This red medicine contains, according to a report of this clinic,[2] 8 c.c. of Fowler's solution (solution of Potassium Arsenite) in 6 oz. or 0.44 mg. of arsenic trioxide per c.c. As our patient had taken his arsenic for twenty-four days, we estimated that he had received approximately 127 mg. of arsenic trioxide. While this clinic states that in 10,000 cases of use they have had no difficulty, this is hard to follow in view of the lack of adequate follow-up. While arsenic was a known therapeutic agent in ancient Greece and Rome, and organic arsenicals have been of major importance until the discovery of penicillin in the treatment of syphilis and other protozoan diseases, other uses of arsenic in modern medicine are not many. It is a general protoplasmic poison, slow acting and may interfere with cell oxidation. Soluble salts of arsenic are absorbed from all

President's Letter

A FRESH APPROACH

Occasionally a refreshingly amusing note is added to our sometimes too-somber existence. One such item was brought to my attention recently. It is called "Campaign IGHUGS."

We all have been almost saturated with alphabet names over the years, but this one is so well taken as to attract attention and demand explanation, and certainly some form of action. This one stands for "I'm Gonna Howl 'bout Unnecessary Government Spending."

The program itself, while fronted with a delightful title, is actually very serious-minded. It is a non-partisan program designed to create a vivid awareness of the shocking size of today's taxes: 32 cents out of every dollar earned. The purpose of the campaign is quite simple: to drive against all unnecessary Government spending and thereby help to deflate the enormous tax load.

The campaign is one of several which is planned by the Farm-City Conference Board. This organization is an informal group of public relations people representing business firms, large and small industries, farm organizations, trade associations and similar groups. Their primary objectives are to find ways to improve relationships between urban and rural people, and to develop means by which business and agriculture can work together on projects in the public interest. These objectives, though broad, are extremely worthy, and exemplify the voluntary American way of getting something done.

Nationwide organizations have joined the IGHUGS campaign. Among them is the American Medical Association, the General Federation of Women's Clubs, the National Grange and companies such as International Harvester, General Electric, and the Quaker Oats Company.

The group emphasizes that the IGHUGS campaign is not directed against all taxes. Some taxes will always be necessary, the group feels, but the campaign is directed against waste and inefficiency in Government which makes taxes higher than they have to be.

The campaign is patterned after last year's IGHAT campaign—translated to "I'm Gonna Holler About Taxes." Both campaigns are built on the idea that the voice of the people can accomplish miracles—even to the abolishment of huge amounts of wasteful spending by local, state and federal government.

It seems that the clever and engaging titles of this campaign, like last year's, will make the project catch on rapidly, and it is hoped that the IGHUGS project will be equally as successful as IGHAT was.

It is always stimulating to see American citizens organized for group action, and it is especially delightful to see them work so well toward a worthy goal using such a typically American entertaining title which is still serious and sensible. Their success depends much on the degree of support they can enlist from all other voluntary organizations with similar goals, and the medical profession could easily be a moving part of the IGHUGS campaign.

SUBSIDIZING COST OF ILLNESS

PRESIDENT Eisenhower's health program relating to a Government Reinsurance Corporation appears to be to the best interest of the people if it does effectively promote the present trend toward a coverage of the cost of illness through private and non-profit voluntary health insurance agencies. A few questions arise: If this plan is not a subsidy to health as claimed, what can it do that private enterprise cannot do as well, if not better? Does his basic principle of "free choice of physician" find its way deep into the make-up of the insurance companies which are to be promoted by this plan? Once established, could this Reinsurance Corporation be expanded into a compulsory health insurance scheme for the nation by another administration? Why has he avoided the Bolton plan of making medical expenses deductible from income taxes?

A tax deduction subsidy of this type could be carried out without bureaucratic overhead. Those suffering most from the cost of illness would be the principal benefactors. The amount of subsidy could be varied from a fraction to complete coverage of the costs of medical care and could be varied for different income brackets and for times of changing financial stress. The loss of revenue resulting from even a small coverage of the Nation's medical bill by this method may seem inadvisable at this time to our present government. If this is the case, we physicians should see to it that the details of a tax deduction type of subsidy are worked out for future consideration, should a less economically inclined administration run our government.

MATERNAL MORTALITY FACTORS

THE REPORT of the second year's state-wide study of the Minnesota Maternal Mortality Committee appeared in the February issue of Minnesota Medicine. The published results call for commendation of the practitioners of the state for their almost universal co-operation in supplying the data necessary to prepare case reports for study and evaluation by the committee. Without such co-operation from them, this survey could not be carried out, for as Gordon[†] has expressed it, "In our search for the controllable factors of maternal death we cannot depend upon the statistician alone, but must continue to examine not only the certificate of death but actual case reports."

Study of these case reports has resulted in important observations as to what must be done to reduce maternal mortality further in the state. For example, in reviewing deaths from hemorrhage, which is now the greatest single cause of maternal mortality, it is a matter of concern that blood replacement is still often too little and too late; this in spite of the practical experience with blood transfusions during two world wars and despite the increasing availability of blood. Nor can one condone the surprising incidence of accouchement forcé, a dangerous obstetrical procedure thought to have been generally discarded, as a contributing factor to maternal death from hemorrhage in the second year's report.

An observation may be made also concerning the choice of anesthetic agents used during delivery. The dangers of spinal anesthesia to the pregnant or parturient patient need to be re-emphasized so that other safer anesthetics, including local anesthesia, may be given proper consideration.

The maternal death rate in the state has improved so much that it is lower now than what was considered speculatively to be the irreducible minimum a few years ago. This low rate indicates that, on the whole, physicians throughout the state are giving excellent obstetric care. But it should not lull them into a state of false security so that their vigilance in preventing obstetric disaster lags or their consciousness of responsibility wanes.

There is need for improvement in such basic requirements for good obstetric care as careful and recorded history-taking, general physical and pelvic examinations, internal pelvic mensuration, and basic laboratory examinations. More frequent and adequate consultations will lower the mortality rate, if only by reducing the 40 per cent of unindicated operative deliveries noted in the reported two years of the survey. Efforts to obtain autopsies, even partial autopsies to permit tissue examination, will help to confirm the cause of death in many cases and will discover, at times, the cause of death in obscure cases.

[†] Gordon, C. A.: The maternal mortality remainder. Am. J. Obst. & Gynec., 61:1132, 1951.

The physicians of Minnesota well may be proud of their low maternal mortality rate, due specifically to obstetric complications, of 0.45 per 1000 live births in a twelve-month period in 1950 and 1951. Their pride in giving good obstetric care should encourage them to improve it further. In addition to their own efforts, it is hoped that they will give continued support to the committee of their own medical association which is carrying on the year-to-year impartial study of factors involved in maternal death with particular emphasis being placed on the preventable factors.

James J. Swendson, M.D.

SCIENTIFIC ARTICLES FOR PUBLICATION

THERE are several hundred scientific meetings held each year in the State of Minnesota. A large number of these represent the meetings of the various District and County Medical Societies, Hospital Staff groups, Northern and Southern Minnesota Medical Associations, and specialty groups. At these meetings, there are many fine scientific papers and case studies presented.

The Editors of Minnesota Medicine would welcome more of these papers and case reports for possible publication. The greater the amount of material from which to select articles for publication, the better our journal will be. We would like to have more material from the groups mentioned above, and we would like to stimulate more medical writing. There must be quite a number of physicians throughout our state who have developed special interests in various diseases or phases of medicine. You who have these interests may have real ability in medical writing, and we would encourage you to contribute to Minnesota Medicine. The editors will review your contributions and use those of unusual scientific interest.

Letters to the secretaries of the various organizations are being sent, and in them will be suggestions which may aid in obtaining papers of scientific interest. We would like to have more material from general practitioners and from smaller hospital groups. You who belong to these groups have a tremendous source of supply, and we would encourage you to send more medical writings to Minnesota Medicine.

G. J. Mouritsen

MEDICAL EDUCATION ON TAPE

A NEW kind of medical education could easily become the most important form of postgraduate training within the next decade. The California Medical Association has formed a corporation, the Audio Digest Foundation, 417 S. Hill Street, Los Angeles. This organization is busily producing sound recording tapes of literature reviews in various fields of medicine, a complete medical lecture library, on-the-spot records of medical conventions, and master lecture tapes from the nation's seventy-nine medical schools. These and other recordings in several languages are being sold or rented to physicians on a nonprofit basis.

The armed forces have approved a pilot plan using this medium in both the United States and overseas medical-military installations.

This investment in medicine may become a necessity to individual physicians or medical groups in smaller communities and could raise havoc with the present mass educational programs in the larger medical centers. Would you prefer hearing Paul Dudley White of Boston talk on "Rheumatic Heart Disease," or Joe Doke of your city?

EXERTION AND ANGINA

Precordial pain is variously and often confusingly described by the patient. In making a diagnosis, a physician requires detailed information as to the character, distribution, and factors related to the pain, in the absence of objective signs. Exertional pain may be described as a dull ache, a burning, or as an intense pain sensation. It is usually substernal and may affect either arm or both. Such pain is attributable to some exertion that adds to the workload on the heart. The amount of exertion that causes discomfort to the patient is modified by many factors that sometimes seem extraneous, such as the weather, the season, time of day, whether the activity is pleasurable, and the patient's excitement or lack of it. Differentiation of heart pain is important to the diagnosis and to the subsequent instruction, care, and protection of the patient.—Bond, G. S.: Differentiation of precordial pain. Postgrad. Med., 14:233 (Sept.) 1953.

FAMILY DOCTORS' DAYS

Last spring we initiated a series of Family Doctors' Days at the University Hospitals. Members of the Medical School Faculty had long sought a means whereby they could meet more or less regularly with physicians in active practice in the state in order to discuss problems of mutual interest. The Family Doctors' Day idea seemed admirably suited for this purpose.

To date Family Doctors' Days have been presented by the following departments or divisions: Medicine, Surgery, Psychiatry, Physical Medicine and Rehabilitation, Obstetrics and Gynecology. and Radiology. Attendance has been variable, but in general the response has been very favorable. Many physicians who have attended one or more sessions have indicated that they enjoyed meeting with the faculty in this informal way. Faculty members in turn have been warmly enthusiastic.

After almost a year's experience, our ideas about the Family Doctors' Days have crystallized somewhat. We are most anxious to continue them, and we plan to present one each month throughout the year with the possible exception of July and August. Although in most instances the host department or division will present a program dealing with some topic of general medical interest, we do not look upon these sessions as *primarily* educational in nature. Rather, we look upon them as welcome opportunities for meeting the men who practice in our state and for exchanging viewpoints, ideas, and aspirations with them. We do not believe that the Family Doctors' Days in any way supplant the Continuation Medical Education program. Naturally we also hope that no physician will feel that, because of this program, he is less welcome at the many other Medical School activities such as special lectures, conferences, seminars, and ward rounds, all of which are always open to interested doctors.

Advance announcements of the Family Doctors' Days are now carried in MINNESOTA MEDICINE and other publications seen regularly by Minnesota physicians. In most instances individual announcements are also sent to members of the Minnesota State Medical Association. These announcements frequently accompany announcements of medical continuation courses. Since Family Doctors' Days are usually held just after a continuation course has ended or just before one is to begin, we hope that many physicians will find it convenient and profitable to take in both events during their stay in the Twin Cities.

We are naturally pleased when a particular Family Doctors' Day attracts a large number of physicians. On the other hand, if only fifteen or twenty attend, we by no means consider the session disappointing since the smaller group gives us an even better opportunity to become personally acquainted with those participating.

In short we have been very pleased with the Family Doctors' Days and the way in which they have been received. I would like to extend again a most cordial invitation to all physicians to attend as many Family Doctors' Days as possible. I would also welcome any suggestions as to how these sessions could be improved or made more effective.

George Earl, M.D., Chairman

ECONOMIST PREDICTS GOOD YEAR

Mr. O. F. Litterer, business economist of the Federal Reserve Bank in Minneapolis, predicted a leveling of the present temporary recession which would develop into a good business year.

Speaking at the annual County Officers' meeting of the Minnesota State Medical Association in St. Paul on February 13, Mr. Litterer gave several reasons for refuting the pessimistic attitude on business conditions expressed by some. One of the important factors in this area is the farm income situation. "In spite of the problems of surpluses," Mr. Litterer said, "the U. S. Department of Agriculture has characterized the agricultural outlook for 1954 as regaining stability."

Also, he pointed out, prices of farm products have been stabilized, so have farmers' costs. Consequently, farmers' income in 1954 should be close to the 1953 level. Because farmers' debts are low in relation to their total assets, farmers are still in a strong financial position.

Speaking of the recent increase in unemployment in this area, Mr. Litterer explained that much of it is due to seasonal variations; many industries always reduce their labor forces during the winter. In addition, he said, a few industries not of a seasonal nature have reduced the number of their employes due to accumulation of heavy inventories, and they must stop production and put inventory products on the market.

In the housing situation, the contracts awarded last fall in this district were running well ahead of the previous year. The market is holding up much better than expected.

Stabilizers Noted

Because of the absence of many economic stabilizers in the economy during the last depression, the economic structure was very seriously upset. However, Mr. Litterer emphasized, "stabilizers have been built into the economy since the Great Depression of the early thirties." These stabilizers arise out of the large federal budget, the nature of our tax system, the social security program, and farm price support programs, he continued, but he pointed out that he was not passing judgment on the wisdom of these government programs.

He enumerated the following stabilizers in the monetary and credit system:

1. Bank deposits are insured. Bank failures in the 20's and 30's, not bolstered by federal deposit insurance, added greatly to the severity of the depression.

2. Commercial banks are in excellent condition.

3. Federal Reserve banks have been given additional powers to cope with emergencies. They may extend credit to member banks by accepting any collateral which is satisfactory to Federal Reserve officials.

4. Changes have been made in the field of mortgage lending. The typical mortgage loan now has a maturity of 15 to 25 years, as compared with the five to seven years typical in the twenties.

THREE-DIMENSIONAL PR, GOAL FOR 1954

Three dimensions of medical public relations have recently been described by the Public Relations department of the American Medical Association. They are policy, program and promotion.

According to the PR department, to add "three-D" to medical public relations, every physician must become increasingly aware of the importance of public relations—not only in medical society activities, but in his individual practice.

Three goals have been set up to accomplish the best three-D public relations:

"Goal One—Concentrate on spreading the public relations concept more widely throughout the medical profession.

"Goal Two—Develop a stronger, more unified profession.

1. Plan society programs for new members.
2. Revitalize all medical societies to increase society participation.
3. Present a united front on medical issues, supporting the stand of organized medicine on campaigns of national scope.
4. Increase society and individual community participation; sponsor good citizenship and get-out-the-vote campaigns. Remember—1954 is an important congressional election year.
5. Work with medical students, interns and residents, aiding Student AMA chapters, making available material on socio-economic subjects and public relations, and sponsoring PR courses.
6. Reduce the evils of professional jealousy and unwarranted criticism of one M.D. by another. Such actions harm all doctors in the eyes of the public.

"Goal Three—Utilize every PR outlet to tell medicine's positive story.

1. Present radio and TV programs, using AMA transcriptions or films or developing local shows.
2. Sponsor health forums in co-operation with newspapers.
3. Continue to develop good press co-operation and when possible suggest ideas for local features on medical subjects.
4. Reactivate your society's speakers bureau.
5. Prepare leaflets describing local medical facilities for newcomers.
6. Place medical exhibits at fairs and public gatherings.
7. Capitalize on the PR potential of the Woman's Auxiliary in carrying through society projects.

"Goal Four—Mend PR fences to eliminate complaints about medicine.

1. Set up mediation committees with 'teeth' to actually discipline those few unethical MDs who damage the reputation of the whole profession. Publicize these committees.
2. Make sure your community has a working, well-publicized night and emergency telephone call system.
3. Encourage establishment of medical audits and tissue committees in hospitals to combat widespread publicity regarding ghost surgery and fee splitting.
4. Promote voluntary health insurance and develop closer liaison with such insurance programs; reduce physician abuses of such plans.
5. Offer through your society a guarantee of medical care for all, regardless of ability to pay, and be prepared to make good on that guarantee when necessary.
6. Set up training programs or work with organized medical assistants' groups to teach the importance of medical PR.
7. Encourage greater use of AMA plaques to stimulate fee discussions in the doctor's office and thus reduce fee misunderstandings."

NEW PENSION BOOKLET

The Bureau of Medical Economic Research of the American Medical Association has just issued a new booklet entitled "Prepaid Pensions for All." The booklet is a result of recent questions raised by physicians on the differences between the Jenkins (Reed)-Keogh bills before Congress and other proposals to force self-employed physicians and others under the Old Age and Survivors Insurance tax and benefit provisions of the Social Security Act.

Frank Dickinson, Ph.D., director of the bureau, provides factual material on present prepaid pension plans and the proposed Jenkins-Keogh bills which would allow the self-employed to arrange their own pensions. At the present time, there are two Congressional acts providing retirement income for millions of persons. These are Title II of the Social Security Act of 1935 (Old Age and Survivors Insurance), and Section 165(a) of the 1942 Federal Internal Revenue Code.

How It Works

Explaining briefly how the OASI retirement fund works, the pamphlet states:

> "Employes in covered employment contribute a small percentage of their earnings up to $300 a month (at present, 2 per cent) to the OASI Trust Fund; this amount is matched by the employer. On the same earnings, covered self-employed workers contribute an amount equal to three-fourths the combined tax of the employer and employe."

And, according to Dr. Dickinson, this type of plan is not yet strictly prepaid. He states: "Beneficiaries *now* on the OASI rolls have prepaid (with their employers) only one twenty-fourth of the costs of the benefits they are receiving—scarcely enough to cover the administrative costs. (The source of the 1 to 24 ratio is the report of the Curtis Subcommittee on Social Security of the House Committee on Ways and Means.)"

In Section 165(a) of the Federal Internal Revenue Code, the employer pays for the pension in a noncontributory plan and both the employer and employe pay in the contributory plan. These are completely prepaid.

However, the pamphlet asks this question, "Who bears the burden of employer contributions to OASI and/or Section 165(a) plans?" And the pamphlet answers its own question:

> "The contributions, as a part of employers' costs, are shifted to the consumer in the form of higher prices. The consumer paying for these benefits may be one of the 11 million self-employed who do not benefit under either category or one of the 30 million pensionless employed who do not benefit from a tax-exempt pension plan."

A More Equitable Plan

The pamphlet states that the Jenkins-Keogh, and identical bills, are the answer to making this pension problem more equitable. It also points out that these bills, H.R. 10 and 11, do not amend the Social Security Act, but would amend the internal revenue law. "Hence it should not be confused with proposed changes in the Social Security Act," the pamphlet emphasizes.

How It Would Work

H.R. 10 and 11 would work thusly: Self-employed and pensionless employed persons would be permitted to set aside, tax-free, a limited portion of their earned incomes into individual retirement trust funds; taxes will be paid upon the withdrawal (usually as pensions) of these funds. The result would be tax deferment similar to that on employers' contributions to tax-exempt plans approved by the Bureau of Internal Revenue under Section 165(a). Ten per cent of earned income (but not more than $7,500) may be excluded annually from taxation under this plan. Furthermore, a lifetime limit of $150,000 would, in effect, prevent financing a pension of more than $1,000 a month starting at age seventy. The accumulated money may be withdrawn from the restricted trust fund in a lump sum or in installments, and all withdrawals are taxable income.

In summary, the pamphlet states: "Repeal of Section 165(a) as a method of obtaining equity for the self-employed and the pensionless employed would be a cruel and nonprogressive step to destroy this rapidly growing plan for old-age protection. The only reasonable solution is to provide the self-employed and pensionless employed the same tax-deferment advantages and privileges as are now enjoyed by those covered by pension plans under Section 165(a)."

> "H. R. 10 and 11, the 'Individual Retirement Act,' will provide the means to restore equity; *prepaid* financial security for old age would then be possible for all Americans. A generation after this pending legislation is enacted, much of the need for non-prepaid pensions for an aging population will have been met by prepaid pensions. This is what OASI was supposed to do, but has not. Perhaps it never could.
>
> "For it may be inherently impossible for a government operated program to achieve prepaid pensions for all. The wiser program may be for the government to provide the maximum encouragement for private pension plans, both individual and group."

DOCTOR BILLS MADE LESS PAINFUL

There is a doctor in Portland, Oregon, who has initiated a clever technique to smooth out the rough kinks in his relationships with his patients. More than a year ago this general practitioner began sending a warm, chatty letter with the bills he mailed to his patients. The idea clicked immediately. He now mimeographs and mails more than 400 "newsletters" each month, not only to patients who owe him money but also to many who do not.

The text of the beginning of the first letter is as follows: "Dear Friends: The thought has occurred to me that opening a stack of bills around the first of the month can be pretty unpleasant. . . . This, then, is my attempt to make one of the most unpleasant parts of medical practice a little less so.

"My plan is to enclose a letter like this with each bill. In these letters I'll try to keep you informed about medical matters that I think you'll be interested in. . . ."

The doctor's letters discuss everything under the sun: immunization, polio, obesity, emergency operations, appointments, parking at the doctor's office, diet, toddlers, big kids and adults, baby and child care, how to stop worrying, hygiene, colds and nose drops, chickenpox, measles and politics.

This type of public relations is one of the most valuable of all for the medical profession. It handles people like they wish to be handled—with a human touch. Its value is especially important because it is practicing good public relations at the right level: the doctor's office.

Minneapolis Surgical Society

Meeting of November 5, 1953

The President, Robert J. Tenner, M.D.

GASTRIC SARCOMA

HAROLD G. BENJAMIN, M.D.
Minneapolis, Minnesota

EWING defines sarcoma as a malignant tumor composed of cells of the connective tissue type. We are inclined to think of this tumor as being a rare lesion. However, a survey of recent literature indicates that sarcomas may comprise 3 per cent of all malignant gastric neoplasms, and therefore must be considered in the differential diagnosis of tumors arising in the stomach. We shall never know how many sarcomas have been returned from the operating room with the mistaken diagnosis of "inoperable carcinoma."

The duration of life following the discovery of a gastric sarcoma may be quite long, even though a complete cure is not obtained. Their response to treatment is favorable and the importance of their recognition should be emphasized.

A uniform classification for sarcomas has not yet been adopted and this fact leads to some confusion in the discussion of these tumors. Perhaps the most satisfactory classification is a modification of Ewing's.

I. *Spindle Cell Sarcoma*
  (a) Leiomyosarcoma
  (b) Fibrosarcoma
  (c) Neurofibrosarcoma

II. *Lymphosarcoma*
  (a) Reticulum cell sarcoma
  (b) Malignant lymphocytoma (small round cell sarcoma, lymphocytic type lymphosarcoma).

Lymphosarcomas account for approximately 60 per cent of all gastric sarcomas.

From the surgeon's point of view, gastric sarcoma is a localized tumor and should be resected. The average survival period following surgery for gastric sarcoma is much longer than that following surgery for gastric carcinoma. During the years 1945 to 1952, there were ninety-three cases of gastric maligancy admitted to Northwestern Hospital in Minneapolis. Of these, eighty-eight were carcinoma, and five were sarcoma.

I would like to report in some detail a case of sarcoma which came under my care. Like nearly all other sarcomas reported, the diagnosis in this case was not made pre-operatively, but there are certain features of the history and examination which sometimes make this diagnosis possible.

Case Report

This patient was a woman, aged fifty-four, who was first seen in the early part of June, 1949. At that time, she stated she had noticed a vague epigastric pain with occasional nausea and vomiting during the previous year. For one week prior to admission, the pains had become quite severe, and she had noticed the stools were black. She was nauseated most of the time and could retain only milk. On one occasion, she vomited a little blood. Food did not relieve the pain.

Physical examination revealed a white woman 5 feet 5½ inches tall, weighing 134 pounds. She was thin, nervous, and appeared to be weak and rather chronically ill. Her blood pressure was 116 systolic and 74 diastolic. There was no abnormality of the head, neck, or extremities. Her pulse was 76 per minute and regular. The heart and lungs were normal. There was a slight tenderness to deep palpation in the epigastrium, but no masses were palpable and the liver and spleen were not enlarged. The rectal and pelvic examinations were negative.

Laboratory: X-ray examination at that time revealed an area of infiltration on the lesser curvature of the stomach suggestive of an inflammatory lesion rather than a malignancy. Gastric analysis showed free acid 73°, total acid 85°. Urinalysis showed a specific gravity of 1.014, albumin 0, sugar 0, and microscopic negative. Her hemoglobin was 13.5 grams, with a white blood cell count of 5,400, and a normal differential. The Wassermann test was negative.

Treatment: She was placed on a modified Sippy diet, rest, and antacids. Radiographs taken on June 30, 1949, showed a small ulcer crater on the lesser curvature of the stomach about 2 inches above the pylorus with a moderate amount of induration about it. At that time the diagnosis was gastric ulcer.

Medical management failed to result in any substantial reduction in pain or discomfort. The patient eventually consented to a subtotal gastric resection and she was operated upon on October 27, 1949. At the time of the

GASTRIC MALIGNANCY
Northwestern Hospital, Minneapolis
1945—1952

Age	*Carcinoma*	*Sarcoma*
0–20	0	0
21–30	0	0
31–40	2	1
41–50	4	1
51–60	18	1
61–70	31	1
71–80	27	0
81–90	6	1
	88	5

operation, a small area of induration 2 cms. in diameter was found on the lesser curvature of the stomach 2 inches above the pylorus. The gross appearance seemed to confirm the diagnosis of peptic ulcer. Approximately two-thirds of the distal end of the stomach was resected, using a Hoffmeister modification of the Polya type of repair and a retro-colic anastomosis to the jejunum. One small lymph gland was found along the lesser curvature of the stomach at the time of its removal.

Pathology: The macroscopic specimen showed the distal portion of a stomach, measuring 12.5 cm. along the lesser curvature and 17 cm. along the greater curvature. At a point about 4 cm. above the distal end of the specimen on the lesser curvature there was the edge of a tan, granular patch 3.5 x 3 cm. The mucosa was slightly thickened and indurated in this area. It had a grey-yellow color and appeared slightly granular. Near the center of this patch there was a sharply limited ulcer, 7 x 6 mm. and 2 mm. deep. The wall of the stomach was of average thickness and consistency.

Sections from the pyloric portion of the stomach show that the mucosa was moderately infiltrated by lymphocytes and plasma cells. Sections made at the junction of the tan granular area and the apparently normal antral mucosa, showed an increasingly intense lymphocytic infiltrate. The ulcer has a necrotic floor with many neutrophiles. Sections from the center of the tan patch show the mucosa to be replaced by medium-sized lymphoid cells with a few mitoses and a moderate number of eosinophiles. The mesenteric node showed only benign hyperplasia.

The diagnosis was early lymphosarcoma of the stomach with ulceration.

The patient's postoperative course was uneventful. She has continued to be in good health except for a susceptibility to colds and viral infections. Fluoroscopic and film examinations made two years after operation, on September 26, 1951, showed the esophagus to be normal. A partial gastric resection was noted with a normally functioning anastomosis. There was no evidence of an ulcer or other abnormality.

Because of the small size of the lesion and the fact that it was an early lymphosarcoma with no evidence of metastasis or local extension, no radiation was given postoperatively. It is now four years since the operation and the patient remains in good general health.

Ewing ventured the opinion that lymphosarcoma may begin as an inflammatory process. It is interesting to note that since he made this observation, nothing has been suggested to relate peptic ulcers and sarcomas. It is generally believed that ulceration of the lesion is due to necrosis within the tumor itself.

The clinical and laboratory findings should be studied carefully since the possibility of arriving at a diagnosis of sarcoma of the stomach before operation resides in these features:

1. Epigastric pain is nearly always the major complaint.
2. Hemorrhage is frequent; more often melena than hematemesis.
3. The general condition of the patient is often comparatively good since the lesion usually localizes away from the gastric orifices and obstruction does not develop early.
4. The average age is forty-five, while for cancer it is fifty-five or sixty.
5. The x-ray findings of a filling defect with smooth margins, or of diffuse types with rigidty of the walls and infiltration, plus the presence of giant rugae; or of the presence of two or more defects in the mucosa; are all suggestive of gastric sarcoma.
6. It may be possible to procure a specimen for biopsy by esophagoscopic examination, but frequently visualization alone cannot differentiate the lesions.
7. The absence of free acid in the stomach is significant in its relationship to the presence of sarcoma and carcinoma alike.

Sarcoma occurs in a younger average age group than does carcinoma. In a series of sarcomas reported Pack, the average age was forty-five years. In Broder's series, the average age was fifty years; and in Walter's series, the average age was 43.7 years. The youngest case of gastric sarcoma seen at the Mayo Clinic was ten years and the oldest was sixty-eight. In this series of gastric sarcomas, the extremes were thirty-seven to eighty-three years of age.

The average duration of symptoms in forty-one cases of gastric sarcoma seen at the Lahey Clinic between 1929 and 1949 was ten months, with extremes of from three weeks to four years. These cases were all of the sarcomas seen in 1,171 operations for malignant tumors of the stomach during that interval.

It is generally believed that sarcomas metastasize by way of the blood stream with the exception of lymphosarcomas, which may spread by direct extension or by the lymphatics.

In most cases reported, the tumor could not be diagnosed by the gross specimen as to whether it was carcinoma or sarcoma. It is usually necessary to examine the tissue microscopically in order to establish the diagnosis. This accounts for the difficulty in x-ray or endoscopic diagnosis.

Grossly, the lesion may be divided into four types as suggested by Pack and McNeer:

1. Single bulky polypoid growths well demarcated from the stomach.
2. Solitary or multiple ulcers with surrounding infiltration.
3. Multiple nodular tumors of the stomach.
4. Diffuse thickening of the wall of the stomach.

The lesion in this discussion falls under Group 2.

These tumors may grow very rapidly or at other times exceedingly slowly. The lymphosarcomas generally pursue a more rapid growth. They arise in the submucous layers of the stomach and infiltrate the surrounding layers. Probably their proximity to the submucous plexus of nerves and their early infiltration into the muscle layers of the stomach accounts for the prominent and early symptom of pain.

At operation, the lymphosarcomatous mass, if large, is usually firm and may be necrotic, friable, nodular and rubbery. If secondary infection sets in, chills and fever may be a symptom. Metastases to the regional lymph nodes are frequent.

Treatment

Therapy falls under the two main headings of surgery and radiation. Subtotal gastrectomy is accepted as the treatment of choice for all but the most advanced cases. Probably more frozen sections should be done at the time of operation, where grossly malignant lesions of the stomach are encountered. This is particularly true when a sarcoma is suspected. If the lesion proves to be a sarcoma, the surgeon should make every effort to resect the stomach. Some lesions appearing to be an inoperable carcinoma, have been found to be sarcomas quite amenable to resection.

McSwain and Beal (Ann. Surg., 1944) state that "roentgenotherapy should be given in every case of lymphosarcoma of the gastrointestinal tract unless the operator and the pathologist are certain that the lesion has been completely eradicated." A combination of the two is most frequently effective. In the case reported, it was felt that all of the lesion was removed because of its early stage and absence of demonstrable metastases.

Sarcomas are far more sensitive to deep x-ray radiation than carcinomas. In diffusely infiltrative, non-ulcerated types, as in the aged and debilitated, or in already metastasized lesions, the case may more rightly be considered one for radiation therapy than for surgical intervention. Postoperative radiation should be started as soon as the wound is healed.

The surgeon who encounters a large infiltrating mass and is inclined not to resect, must consider the possibility that the lesion may be a sarcoma. As long as this tumor cannot be excluded, the patient should be given a chance for the more favorable prognosis which a resected and radiated sarcoma carries.

Conclusion

In conclusion, then, it has been my purpose to emphasize that sarcomas must be considered in the differential diagnosis of gastric tumors. A uniform terminology for their description is needed. Their consistent symptoms of severe pain, and hemorrhage, in a relatively slightly cachectic individual in the younger age group, plus the suggestive x-ray and gastroscopic appearance, should make a pre-operative diagnosis more common. Gastric resection plus x-ray radiation offers a very good chance of long palliation and occasionally a cure.

The case report of another gastric lymphosarcoma has been added to the literature on this subject.

History of Medicine In Minnesota

MEDICAL HISTORY OF THE COUNTY OF YELLOW MEDICINE

MILDRED B. LEE
Granite Falls, Minnesota

(Continued from January, 1954, issue)

Alonzo T. Munro was born at New Auburn, Minnesota, on September 12, 1875, the third son in the family. His parents were Scotch, and had come to the United States soon after their marriage. He received his early education in the schools of New Auburn and Glencoe, Minnesota, then entered the University of Minnesota for his medical training. He graduated with his degree in medicine in 1897, and went to Hanley Falls to begin his practice.

Dr. Munro practiced at Hanley Falls and Wood Lake for three years. In 1901 he married Miss Maud A. Force of Madison, a teacher who had been on the staff of the Hanley Falls schools, and also had taught in Echo. In the following year he left Yellow Medicine County for Kalispell, Montana, where he took the position of assistant physician of the Great Northern Railroad, for the division at Kalispell. After a few years there he went to New York for special training in the diseases of eye, ear, nose and throat, and after qualifying as a specialist in this field he returned to Kalispell where he resumed his practice, and continued to serve the railroad in that capacity.

The region around Kalispell, Montana, was sparsely settled and greatly in need of doctors when Dr. Munro located there. He was one of the pioneer doctors of that area. He was a member of the American Medical Association, and at one time was on the Montana State Board of Medical Examiners. He was also a member of the Montana State Medical Association, and was instrumental in organizing the Flathead Medical Society in 1904. He was a member of the Montana Soldiers' Home Board, and a charter member of the state's Fifty Year Club, which honored those who had served the medical profession for that length of time. For many years he was on the staff of the Kalispell General Hospital, and also served as County Health officer.

During the period of his residence in Yellow Medicine County Dr. Munro was a candidate for coroner of Yellow Medicine County, and in the *Canby News* he was described as follows:

> "Dr. Munro is of Scotch origin, and possesses all the manly, upright qualities of that sturdy race. He was born on a farm near New Auburn, Sibley County, Minnesota, Sept. 12, 1875, attended the public schools until 16 years of age, when he entered Stevens Seminary, Glencoe, from which he graduated three years later. He then took up the study of medicine at the University of Minnesota, graduating in 1897, since which time he has practiced the healing art continuously, the last six months at Hanley Falls. If you cast your ballot for Dr. Munro you have voted for an honest man, a clean man, a capable man and a man who refuses to be a hypocrite 'e'en tho the heavens fall.' He should be elected almost unanimously."

Dr. Munro continued in active practice until his death on December 18, 1951, of congestive heart failure.

He was survived by his wife, Maud A. Munro, and three daughters: Mrs. Phil U. Kington, Mrs. Maurice S. Fisher, both of Kalispell, and Mrs. O. A. Bessey of Galveston, Texas.

Dr. Munro was licensed in Minnesota (No. 824) on June 10, 1897. The state medical records indicate that Dr. Munro was in Wood Lake in 1903 and 1905, but the date of his removal from the county is given by his family as 1902, at which time he was practicing in Wood Lake.

Dr. George W. Nichols graduated from the Vermont Academy of Medicine (Castleton Medical College) in 1861, and in the summer of 1871 came to Minnesota where he located in Rochester. His first office there was in his home on the corner of Fourth and Main Streets. Later he bought a residence on Prospect and Fourth Streets and opened an office on Broadway.

While in Olmsted County Dr. Nichols became a member of the Olmsted County Medical Society and of the Minnesota State Medical Society. In 1874 he became coroner of that county and also county physician. According to the Olmsted County Medical History Dr. Nichols was remembered as "a nice man, a good doctor, an all around good fellow," and had an extensive practice. He was married in 1864, and had a daughter, Edith, and one son.

Dr. Nichols also was a member of the city board of health of Rochester, and of the Independent Order of Odd Fellows, and Ashlar Lodge No. 23 of the Ancient Order of United Workmen.

In 1879 Dr. Nichols bought a farm in South Dakota, then sold his Rochester home and removed to Wahpeton, South Dakota. In 1883 he moved from Wahpeton to Minneapolis where his daughter, seven years old, died. A few months later he moved to Belle Plaine, and in December, 1883 to Saint Paul. From 1887 to 1891 he was in Merriam Park; from 1892 to 1895 in Wood Lake, Yellow Medicine County.

Dr. Nichols' first professional notice appeared in the *Granite Falls Tribune* of August 4, 1891, but it is apparent that he had then been established for some time in Wood Lake. The first mention of him is in the July 14 issue: "Dr. Nichols invited us to visit a patient with him, and we can vouch for the rapid transit to and from." From this it may be inferred that he was still equipped with the spirited horse and fine buggy described in the Olmsted County History as:

> "A Dexter side-spring phaeton with a roomy top; a suitable box beneath the seat will accommodate the side curtains and the useful rubber lap blanket. On the dash, directly in the center is firmly fixed a physician's lamp with a powerful reflector of an improved design, calculated as a light unto the doctor as he meanders over the countless mudholes. The carriage is well built, and judging from the short whirl we took in it behind the doctor's fiery horse, Dan, it is as easy riding a vehicle as we have seen in many a day."

Dr. Nichols had received his state license, No. 646 (r) in 1883, and was a member of the state Medical Society. He may also have been a member of the Camp Release Branch of the State Medical Society while in Yellow Medicine County, but all early records of this organization have been lost and such membership cannot be established.

Dr. Nichols had an office in Granite Falls over Nelson and Johnson's Drug Store, and since he practiced in both Wood Lake and Granite Falls he spent a part of the week at the Sullivan House, one of the early hotels of Granite Falls. The family at Wood Lake is mentioned only when "Dr. Nichols' little girl" had measles.

In 1896 Dr. Nichols left Yellow Medicine County to locate in Mille Lacs County. From there he went to Hinckley, Pine County. Still later he moved to California, where he died in September, 1908.

Dr. Martin A. Nelson graduated from the Physio-Medical College of Indiana, Indianapolis, Indiana, in 1894, and was licensed in Minnesota April 6, 1894, License No. 410. He seems to have located in Clarkfield shortly after that date. Medical directories place him in Clarkfield in 1894 and 1896; in 1898 he was in Fertile, Iowa, where he remained for several years.

In 1909 he was in Minneapolis, and did not register with the State Board until 1928.

Dr. Tord Nielsen (also known as Ford Nielsen) was born in Norway on April 25, 1857. He received his early education in that country, then entered the Royal University of Norway (also called the University of King Frederick) and was graduated with a medical degree in 1881. He then came to the United States and was licensed to practice medicine in Minnesota October 11, 1883 (License No. 11). In 1885 he was licensed in North Dakota, and may have practiced in that state for a number of years. Medical records place him in Minneapolis in 1895, but this seems to be an error, for Dr. Nielsen came to Canby in 1894, from Minneapolis.

Dr. Nielsen's first professional card appears in the *Canby News* of March 30, 1894; "Dr. Tord Nielsen, Graduate of Royal University of Norway, Office over the Citizen's State Bank of Canby."

Dr. Nielsen's reputation had preceded him to Canby, for a local man had been successfully treated by him for tuberculosis. It appears that Dr. Nielsen had built up some reputation for himself in Minneapolis because of his success in treating this disease, for the Canby man, who had tuberculosis in an advanced stage, heard of him quite by accident, from a stranger in a railroad station. The treatment prescribed by Dr. Nielsen for this disease is said to have been both severe and dangerous and was called the "lymph treatment," based upon methods and medicines used in Norway. It brought on a period of serious illness which was followed, in this case, by complete recovery and the patient* lived in good health to great age.

Dr. Nielsen was very well educated and considered a good doctor. His success with the treatment of tuberculosis did not, however, continue; for the reason (it was said) that the necessary medicines could not be secured. Although Dr. Nielsen's prospects for building up a practice were very good, it may be that this failure weighed upon him, for he became moody and began to drink to excess, so that his practice and reputation suffered.

Dr. Nielsen's family consisted of his wife, whose former home had been at Fergus Falls, Minnesota, and two children. The boy, Thorulf, came with them to Canby, and there was a girl born in the summer of 1894. After about a year in Canby Mrs. Nielsen returned to her former home with the children, and Dr. Nielsen went to Minot, North Dakota. In 1903 he was, according to medical records, in Kenmare, North Dakota, and also in 1905. He was later reported in Grafton and Edmore, North Dakota. In 1909 his address was not known.

---

*The Yellow Medicine County man referred to was a brother of Mrs. Ole O. Ostensoe, of Canby (widow of Ole O. Ostensoe, attorney, deceased) who related this incident in considerably more detail. She was an intimate friend of both Dr. Nielsen and his wife.

Nicolay Hilmar Scheldrup (Schjelderup) was born in Tovik, Norway, on September 1, 1873, the son of Andrew Martin and Hanna (Hanvig) Schjelderup. The following contemporary biography is taken from a *History of Central and Northern Minnesota* published in 1904:

> "Dr. N. H. Schelderup, who is an exceedingly well finished and widely educated physician of Granite Falls, Minnesota, belongs to the younger generation of physicians who approach the profession not only with bright and gifted minds but keenly polished and thoroughly educated with the best schooling the times afford. Dr. Schjeldrup was born in Tovik, Norway, in 1872 and his father who was a man of much prominence in his day held a government position in Norway.
>
> Dr. Schelderup was the oldest of a family of children and was reared to manhood in Norway, where he graduated from the University of Christiania, one of the great and famous schools of the old world. This was in 1891, and he immediately came to the United States. Some years were occupied by him in both general and medical study, much of the time being under the special direction of Dr. Fenger, a great operative surgeon of this country. The young student for medical knowledge graduated after a thorough preparation in 1897 and at once began practice in Granite Falls. After two years of professional work he took a postgraduate course at the University of Berlin. Dr. Schjelderup became interested with Dr. F. H. Hacking in 1902, and the two associated themselves together professionally under the firm name of Schjelderup and Hacking. They have a well appointed suite of offices over the Nelson Drug Store.
>
> Dr. Schjeldrup is a Republican and was elected coroner, in 1902, in which he is serving his first term. He was married in 1897 to Miss Silvia Odegaard. She was born in Chicago, comes of Norwegian blood, and is the mother of two children, a boy and a girl. She is a bright and charming lady and is very popular as is her husband in the social circles of the city.
>
> Dr. Schjelderup is Vice President of the Western State Bank and one of the principal stockholders in the institution."

Dr. Scheldrup's professional card began to appear in the local newspapers in the early summer of 1897. He appealed to the foreign born by announcing himself as "Skandinavisk Laege" in all his professional notices. His first office was in a building "opposite Hotchkiss' store" on Prentice Street.

In appearance Dr. Scheldrup was a slender young man of medium height and smoothfaced, so that he appeared younger than his years. In later life he wore a goatee in deference to the custom of the time. His hair was reddish, his eyes blue, his personality well adapted to the community and the profession which he served.

When Dr. Scheldrup came to Granite Falls the twin daughters of the pioneer merchant, R. H. Hotchkiss, were often on the street in their wheel chairs. The twins had never walked, and their parents had taken the children to many physicians only to be told that they were paralyzed from the waist down and there was no help for them. Their case was a challenge to a young doctor with ambition and not too much to do, and Dr. Scheldrup undertook to make a study of it, with the understanding that if he could not help the little girls there would be no charge for his services. He found that the hip joints were immovable, and after much study and consultation with specialists in Chicago he tried out a new technique for relieving the condition. After the required surgery and treatment the girls began to walk, first with crutches and then with canes, and eventually made a complete recovery. It was no small accomplishment for a new arrival in the field and Dr. Scheldrup's professional reputation in the community was definitely made.

In September, 1897, Dr. Scheldrup was married to Miss Sylvia M. Odegaard of Chicago, at the residence of J. F. Ireland in Granite Falls. Announcement of this wedding in the *Granite Falls Tribune* was followed by the note that Dr. Scheldrup "is a promising young physician who came here about six months ago and in that time secured a large practice and has many friends."

In the January 18, 1898, issue of the *Granite Falls Tribune* Dr. Scheldrup is quoted as saying the greatest need of the town was for a hospital and sanatorium. He set out to supply the need for a hospital himself by purchasing the old Henry Hill homestead in East Granite Falls, and furnishing it with the necessary equipment. A registered nurse, Miss Marie Agee of Chicago, was placed in charge. The hospital was operated by Dr. Scheldrup privately for the use of his own patients, but other doctors were free to use it also.

By 1900, the needs of the community required a larger hospital, and Dr. Scheldrup sold it to Mr. and Mrs. Walter W. Stoppe (Miss Marie Agee) who occupied it as a residence until it was destroyed by fire. A new hospital was established in the Pinney homestead, a large, two-story building which is still in use as a dwelling on Ninth Avenue, just off Prentice street. Here there was room for additional beds and for a laboratory and operating room.

On July 12, 1898, Dr. Scheldrup's first child, a son, named Albert H. Scheldrup, was born. Dr. Scheldrup's practice was steadily increasing, and the family occupied a large home at 2155 Prentice Street (now known as the Olds residence). The four horses necessary to get the doctor around the country were housed in a barn on the river bank back of the house. The driver who was also a necessary adjunct to the doctor's menage was established in a small room off the kitchen where he could be reached conveniently at any time.

The doctor was interested in civic projects and in the general welfare and progress of the community. He found time to take part in promoting local celebrations and other projects.

Dr. Scheldrup's second child, a son, Amos Stephan, was born August 20, 1901, and in 1904 another child, a girl, Sylvia Louise, was born on August 14.

In 1902 Dr. Frank H. Hacking, then practicing at Wood Lake, Minnesota, was taken into partnership, and this arrangement continued until 1906, when Dr. Scheldrup was invited to take over Dr. F. A. Dunsmoor's surgical practice during his absence. Dr. Dunsmoor was also acting as professor in clinical surgery at the University of Minnesota, and this position was also to be taken over by Dr. Scheldrup during the time Dr. Dunsmoor and his family were away on an extended tour of the European countries. This invitation was accepted, and Dr. Scheldrup terminated his connections in Granite Falls to take over the responsibilities of a wider field.

At this time his domestic affairs were also in crisis; Mrs. Scheldrup commenced an action for divorce and then returned to Chicago with her three children.

Upon his return from Europe Dr. Dunsmoor proposed that Dr. Scheldrup continue to be associated with him, and this proposal resulted in a pleasant and harmonious partnership which lasted for six years. But Dr. Scheldrup began to see the tendency of the medical profession to become highly specialized, not only in internal medicine but also in surgery, and he thought the time had come to follow the trend of the profession and establish a clinic. As an older man Dr. Dunsmoor did not feel inclined to accept this idea, so Dr. Scheldrup carried out his plan and established a clinic with which he was actively associated for many years at 1111 Nicollet Avenue, Minneapolis. When the clinic was formed Dr. Hacking was invited to join it, and accepted. Later through the efforts of Dr. Scheldrup, Dr. Hacking was appointed as the chief tubercular expert at the Thomas Tubercular Hospital, affiliated with and owned by the Fairview Hospital.

About the same time Dr. Scheldrup and a group of friends organized the Fairview Hospital, built it, and made it one of the outstanding hospitals in the state.

Throughout his career Dr. Scheldrup kept abreast of medical developments and steadily sought to perfect the techniques, methods, and services of his profession. Until 1932 he was a surgeon at Fairview hospital and engaged in all the activities necessary to promoting the interests of the hospital and keeping up with the demands of his profession. But the pace which he had set for himself told upon his health; a heart ailment curtailed activities and forced him to retire from active participation in 1932.

Since that time Dr. Scheldrup has lived at 185 S.E. Eighth Street, Miami, Florida, during the winter months, and at his summer home at Rainy Lake in northern Minnesota.

During World War I, Dr. Scheldrup served as Captain, Medical Corps, of the U. S. Army, from 1918 to 1919; he was decorated Knight, Order of St. Olaf, first class (Norway); and is a director of Perfection Manufacturing Company. His name appears in International Blue Book and in Who's Who.

His four children, A. S. Scheldrup, Eugene W. Scheldrup, Sylvia Louise, and Robert, are living at this time. Sylvia Louise is the wife of Dr. Harold R. Leland of Minneapolis.

The doctor is a Republican, and a member of the Lutheran Church of which he has been a loyal and generous supporter. Throughout his career he has kept in touch with valued friends in Granite Falls and is given credit for many acts of charity and kindness.

Dr. N. M. Smith, a doctor of the Eclectic School, was located in Granite Falls in 1873. Rose's History of Yellow Medicine County places him as a resident of East Granite Falls; but a map or sketch of the city made in 1874 shows his house in West Granite Falls. Some old residents remember the Dr. Smith house as the one now standing at the intersection of Ninth Avenue with Third Street, and known as the Stoppe residence.

Dr. Smith's professional cards appeared in the *Granite Falls Journal* until about 1878, when he seems to have moved from Granite Falls to locate in Iowa. The few newspaper items about him indicate that he originally came from Iowa, as both his own and his wife's relatives lived in that state. While in Granite Falls two children were born to the N. M. Smiths.

The libel action which Dr. Smith commenced against the editor of the *Granite Rock* is elsewhere reported. The account of the trial in justice court in Minnesota Falls leaves one with the impression that he was not a skilled physician, and certainly the other members of the profession were not in sympathy with him. Two doctors testified for the defense, and nowhere in the *Minnesota Sentinel* edited by Drs. Stratton and Falk is Dr. Smith referred to as Dr. N. M. Smith.

Dr. F. G. Sparling. In 1896 the village of Wood Lake had a population of 100 people, and one physician, Dr. F. G. Sparling.

He is remembered as a tall, slender young man who ministered to the people of the community through epidemics of measles and other diseases. He did not have a family at that time.

Dr. Sparling graduated from Rush Medical College in 1895, and probably began his medical practice in Wood Lake. He practiced about two years in that village.

In 1901 Dr. Sparling was licensed in Nebraska, and in 1904, in Iowa.

He died in Minneapolis on January 5, 1922, of heart disease, at the age of fifty-seven years.

Albert Burbank Sweet was born at Walden, near Montpelier, Vermont, July 14, 1847. He moved west with his parents in 1851. The family traveled on a home-made flatboat going by way of the Great Lakes to Freeport, Illinois, then by covered wagon to Waukon, Iowa, and to Winona County, Minnesota, in 1854. His early education was probably gained in the schools of that region.

At the age of sixteen he answered the call for volunteers to serve in the Civil War, serving with Company F, of the Fourth Minnesota Volunteer Infantry. He was wounded while accompanying General Sherman on his march to the sea.

After the war Dr. Sweet taught school in Brown County, Minnesota, and during the blizzard of 1873 was marooned for two days in the school house with his pupils. He was credited with saving their lives. He then took up the study of pharmacy and became a graduate pharmacist. He went into business as a druggist in Marshall, Lyon County, where, in 1880, he married Fannie Hortense Simpson. In 1884 the Sweets moved to the village of Hanley Falls, then called Hanley, where he established the first drug store in that village. The "City Drug Store" advertised in the *Granite Falls Journal* and prospered; in 1886 a cousin, also a doctor and a druggist, F. B. Sweet, was taken in as a partner.

During this period Dr. Sweet began the study of medicine at the University of Minnesota, while still retaining his interest in the drug business. He graduated from the Medical Departmnt of the State University in 1884, and was licensed to practice in Minnesota on October 27, 1885 (No. 1117)—Basic Science Certificate No. 3178. He was named surgeon for the Minneapolis and St. Louis Railway at Hanley.

Dr. Sweet was progressive and interested in the development of the new settlement. He is reported as trying to interest Saint Paul people in establishing a bank in Hanley; then he enlarged his drug store, advertised as a "manufacturing chemist" and also practiced medicine. Dr. Sweet was very successful as a druggist; as a young practitioner in Hanley Falls he was not so successful.

Dr. Sweet left Hanley about 1888 or 1889 for Kasota, and later practiced in St. Peter for a time. In 1891 he moved to Minneapolis where he practiced medicine exclusively, and in 1892, settled in Hopkins, the first physician to locate in that place. In 1922 he retired from active practice, but continued his activities in the G.A.R. and V.F.W. until his death. Mrs. Sweet died in 1937.

Dr. Sweet died on July 6, 1943, at the Veterans Hospital, after an illness of one day. He was then ninety-five years old. He was a member of the Minnesota State Medical Association, of the G.A.R. and V.F.W. as above noted. His death was due to cerebral thrombosis and arteriosclerosis. He was buried at Lakewood Cemetery with military honors.

(To be Continued)

✦ Reports and Announcements ✦

AMERICAN GERIATRICS SOCIETY

The eleventh Annual Meeting of the American Geriatrics Society will be held at the Fairmont Hotel, San Francisco, preceding the meeting of the American Medical Association. The scientific sessions of the meeting will begin Thursday afternoon, June 17, and continue through Saturday morning, June 19.

Hotel reservations should be made through the San Francisco Convention and Visitors Bureau, 200 Civic Auditorium, San Francisco 2, California. Members should reserve accommodations immediately, stating date and time of arrival and departure, because the hotels expect to be filled to capacity.

The Annual Business Meeting will be held in the Fairmont Hotel, June 17, 9 a.m. The room where this meeting will be held will be announced later. All Scientific Sessions will be held in the Nob Hill Room of the Fairmont, and the annual dinner is scheduled for the Terrace Room on Friday evening, June 18.

The meeting will be open to all members of the American Geriatrics Society and to physicians and other scientists who are interested in the field of geriatrics. The program will cover many aspects of geriatric medicine, and there will be several panel discussions on such subjects as recent developments in cardiology, methods of determining operability in older patients and the relation of industry to geriatrics. Outstanding clinicians and investigators will participate.

Dr. Laurance W. Kinsell, Highland Alameda County Hospital, 2701 Fourteenth Avenue, Oakland 6, California, is in charge of local arrangements for the meeting.

AMERICAN GOITER ASSOCIATION

The American Goiter Association will hold the 1954 meeting at the Somerset Hotel, Boston, Massachusetts, April 29, 30 and May 1, 1954. The program will consist of papers and discussions on the physiology and diseases of the thyroid gland. For further information write John C. McClintock, M.D., Corresponding and Recording Secretary, 149½ Washington Avenue, Albany, New York.

THE CANCER INSTITUTE AT MIAMI, CANCER RESEARCH AND CYTOLOGY CENTER

Dr. Joseph S. Stewart, chairman of the third annual Seminar and Conference of Cancer Cytology to be conducted by the Cancer Institute at Miami, announces that the conference will be held April 21-24, 1954, inclusive.

This year the conference will bring together several leading authorities on cancer from this country and abroad. The last day will be devoted to a special session for medical practitioners, who will visit the Cancer Institute to see demonstrations on the taking and preparation of cytodiagnostic tests for cancer of many types, with special sessions devoted to cancer of the uterus, breast, prostate, lung, and stomach. The latest advances in cancer diagnosis using new cytological methods and blood testing procedures will be presented.

Members of Dr. Stewart's Committee include: Dr. Virgil H. Moon, honorary chairman; Dr. Richard Fleming; Dr. Ralph W. Jack, and Dr. Milton Coplan. The program will be conducted under the direction of Dr. J. Ernest Ayre.

CHEST DISEASE SYMPOSIUM FOR GENERAL PRACTITIONERS IN SARANAC LAKE THIS SUMMER

The third annual Symposium on Tuberculosis and Other Chronic Pulmonary Diseases for General Practitioners will be held in Saranac Lake, New York, July 12 through 16, 1954. It is approved by the American Academy of General Practice for twenty-six hours of formal credit for its members.

The Symposium is sponsored by the American Trudeau Society, the Saranac Lake Medical Society and the Adirondack Counties Chapter of the New York State Academy of General Practice. The registration fee is $40 for A.A.G.P. members and $50 for nonmembers.

The scope of this year's Symposium has been broadened to cover chest diseases other than tuberculosis. Included in the course will be discussions of the diagnosis and treatment of nontuberculous pneumonias, pulmonary cancer, lung abscess, fungus diseases, bronchiectasis, sarcoid, cystic disease, emphysema, and the pneumoconioses.

The speakers and panel members at the Symposium will include thirty-four physicians, surgeons, and scientists from Saranac Lake and surrounding areas. Guest lecturers include Dr. D. Ewan Cameron, professor of psychiatry, McGill University, Montreal, and Dr. Donald Miller, assistant professor of thoracic surgery, University of Vermont Medical School, Burlington, Vermont.

Many physicians who have attended previous symposia have brought their families to Saranac Lake. So that families might have use of the car to enjoy the many recreation and vacation facilities of the Adirondack Mountains, free bus transportation was provided for physicians from Saranac Lake to the various meeting places. This practice will be followed again this year.

These Symposia are the result of many requests, during the last few years, from the General Practitioners for a postgraduate course on chronic pulmonary diseases designed for them and presented over a period short enough so that they might readily attend. The 1954 Symposium has been planned to meet those needs and to cover all important aspects of these diseases from the General Practitioner's point of view.

Many of the sessions are informal panel discussions with ample opportunities for questions from the audience.

The Symposium will be held in various sanatoria and laboratories in the Saranac Lake area. Morning sessions will be from 8:30-12:30 and afternoon sessions from 2:00-4:00 (Monday, Wednesday, and Thursday). There will be elective sessions on Tuesday and Friday afternoon. Physicians desiring to make patient rounds will have that opportunity each afternoon at 4:00. On Monday, July 12, there will be a dinner for physicians attending the course, their families, and faculty.

Complete information concerning this program can be obtained by writing: Richard P. Bellaire, M.D., Chest Disease Symposium, P.O. Box 2, Saranac Lake, New York.

PAN-PACIFIC SURGICAL ASSOCIATION SIXTH CONGRESS

Doctors are cordially invited to attend the Sixth Congress of the Pan-Pacific Surgical Association to be held in Honolulu, October 7-8, 1954, and are urged to make arrangements as soon as possible if they wish to be assured of adequate facilities.

An outstanding scientific program with over 100 leading surgeons, including sessions in all divisions of surgery and related fields, promises to be of interest to all members of the profession. An extensive social program is being developed for the doctors' families.

The Association office has been appointed as travel agent for those attending the Congress and it is important that all hotel and travel reservations be made through the Honolulu headquarters of the Pan-Pacific Surgical Association.

For further information, please write to F. J.. Pinkerton, M.D., Director General, PAN-PACIFIC SURGICAL ASSOCIATION, Suite Seven, Young Building, Honolulu, Hawaii.

INDUSTRIAL HEALTH CONFERENCE

Significant industrial health problems, ranging from increasing incidence of lung cancer to industrial absenteeism, will be discussed in a five-day session at the annual meeting of the Industrial Medical Association, April 26 to 30, at the Sherman Hotel, Chicago.

This large meeting will be attended by more than 2,000 delegates to the 1954 Industrial Health Conference, which also includes gatherings of the American Association of Industrial Nurses, Incorporated, the American Association of Industrial Dentists, American Industrial Hygiene Association and American Conference of Governmental Industrial Hygienists.

After registration on April 26, the meeting of the Industrial Medical Association will open with clinics on April 27. That afternoon, the opening session will feature papers on health in industry, plus a panel discussion.

April 28, the IMA will meet jointly with the American Industrial Hygiene Association to consider "The Responsibility of the Profession in the Health Education of the Employee."

That afternoon, in a joint session with the nurses and dentists, the Industrial Medical Association will discuss causes of absenteeism.

April 29, the Surgical Section will center its discussion around major surgery of the extremities and the relationship of the Industrial Medical Department and Civil Defense. Meeting simultaneously, the Medical Section will hear papers on "Lung Cancer" and "Cardiacs in Industry."

Plant tours will climax the meeting on Friday.

Theme of the 1954 Industrial Health Conference is "Protecting our greatest industrial wealth—employee health." The conference has been described as a "post-graduate course, covering the entire field of industrial health and hygiene, occupational ailments and traumatic surgery."

SCHOLARSHIPS IN PLASTIC AND RECONSTRUCTIVE SURGERY

The Foundation of the American Society of Plastic and Reconstructive Surgery announces the regulations of the Fifth Annual Scholarship Contest:

1. The contest in *Junior* Classification is restricted to residents in training and to plastic surgeons who have been in practice *no longer than five years.*
2. Two main prizes are offered, each consisting of a *three-months' plastic surgery scholarship* with full maintenance in a number of selected leading services, in the United States and abroad.
3. The subject matter of the essay must be the result of some *original* research (either clinical or experimental) in the field of plastic and reconstructive surgery. Thesis should be of about 5,000 words, and written in English.
4. Work previously published wholly or in part is not acceptable.
5. Expenses of travel between the services will be allotted.
6. A silver plaque or a certificate of honorable mention is also offered for a winning essay in *Senior* Classification to contestants active in practice of plastic and reconstructive surgery for *more than five years.*
7. Manuscripts will not be accepted by the Award Committee *after July 1, 1954.*
8. The winning essays will be presented in person at a formal program of the Foundation of the A. S. of P. and R. S. to be held in the Fall of 1954.

The 1953 Scholarships were awarded to the following: Robert M. McCormack, M.D., Rochester, N. Y., for an Essay, "Simultaneous Chordee Repair and Urethral Reconstruction for Hypospadias."

James Calnan, F.R.C.S., Oxford, England, for an Essay, "The Error of Gustav Passavant," Sub-title: "A Refutation of the Recognized Velo-Pharyngeal Mechanism in Speech."

For further information, write to the Award Committee, c/o Jacques W. Maliniac, M.D., Chairman, 30 Central Park South, New York, N. Y.

FAMILY DOCTORS' DAYS

University of Minnesota Hospitals

All physicians are cordially invited to attend the following Family Doctors' Days which will be presented under the direction of the department indicated.

March 10—Dermatology
April 7—Pediatrics
May 5—Hospital Laboratories
June 9—Pathology

Activities begin with luncheon at 12:00 noon with the staff of the department in the Hospital Dining Room and will continue throughout the afternoon.

For further information, write the head of the department concerned or the Director, Department of Continuation Medical Education, 3330 Powell Hall, University of Minnesota.

REGIONAL MEETING OF THE NATIONAL GASTROENTEROLOGICAL ASSOCIATION

A regional meeting of the Central Region of the National Gastroenterological Association will be held in Milwaukee, Wisconsin, March 28. 1954. The scientific sessions will be held at the Hotel Schroeder at 2:00 p.m., following the semi-annual meeting of the Association's National Council.

Participating in the meeting will be Dr. J. Arnold Bargen, Rochester, Minn.; Dr. H. B. Benjamin, Milwaukee, Wisc.; Dr. Carl W. Eberbach, Milwaukee, Wisc.; Dr. James A. Ferguson, Grand Rapids, Mich.; Dr. Robert McCarty, Milwaukee, Wisc.; Dr. Karver L. Puestow, Milwaukee, Wisc.; Dr. James Smith, Milwaukee, Wisc.; Dr. Gerhard Strauss, Milwaukee, Wisc.; Dr. Philip Thorek, Chicago, Ill. and Dr. Marvin Wagner, Milwaukee, Wisc.

Dr. Sigurd W. Johnsen, Passaic, N. J., president, and Dr. Lynn A. Ferguson, Grand Rapids, Mich., president-elect of the National Gastroenterological Association, will preside at the sessions. Dr. Michael W. Shutkin and Dr. Joseph Shaiken, both of Milwaukee, are the chairmen of the program and general arrangements committees, respectively.

The Central Region is comprised of the states of Illinois, Indiana, Iowa, Kansas, Michigan, Minnesota, Missouri, Nebraska, North Dakota, Ohio, South Dakota and Wisconsin.

Members of the medical profession are cordially invited to attend. A copy of the program may be obtained by writing to Dr. Joseph Shaiken, 536 West Wisconsin Ave., Milwaukee 3, Wisc., or to the Secretary, National Gastroenterological Association, 33 West 60th Street, New York 23, N. Y.

CRIPPLED CHILDREN'S SERVICES

The attention of practitioners, throughout the State of Minnesota, is called to the fact that the Crippled Children's Services spring orthopedic field clinics began in February of this year. The following is the schedule of clinics:

Spring Clinic Schedule

St. Cloud*	February 27	Technical High School	Benton Stearns
Cloquet†	March 17 & 18	Civic Center	Carlton Cook So. St. Louis Lake
Faribault†	March 23	Bethlehem Academy	Carver Dakota Goodhue Rice Scott Steele Waseca
Brainerd*	March 27	Franklin Jr. High	Crow Wing Wadena
Hibbing†	April 1 & 2	Village Health Dept.	St. Louis West Range
Worthington*	April 10	Grade School	Cottonwood Jackson Murray Nobles Pipestone Rock
Albert Lea†	April 20	Hawthorn School	Freeborn
Grand Rapids†	April 23 & 24	Court House, County Nurse's Office	Itasca
Austin†	May 4	High School, Nurse's Office	Dodge Mower
Detroit Lakes*	May 8	Rossman School	Becker Clay Mahnomen
International Falls†	May 14	Holler School	Koochiching Lake of the Woods
Thief River Falls*	May 22	High School	Kittson Marshall Pennington Red Lake Roseau
Morris*	June 5	High School	Bigstone Douglas Grant Pope Stevens Traverse

*County Welfare Board Social Service for clinic intake arranged by Field Representative. All *new* patients are requested to bring referrals from their family physicians.

†Social problems arising at clinic will be referred to County Welfare Board on day of clinic. Intake service *not* necessary from County Welfare Board. Gillette patients should not be invited to these clinics. New patients are requested to bring written referrals from their family physicians. *All* patients should have appointments arranged through local Public Health Nurses.

Children may be referred, for consultation purposes, to any of these clinics. A written referral would be appreciated. The clinics are sponsored by Crippled Children Services of the Medical Services Division of the Department of Public Welfare of the State of Minnesota.

RUSSELL M. WILDER FELLOWSHIP

A three-year, $15,000 fellowship, for post-doctorate training in the science of nutrition has been established as the Russell M. Wilder Fellowship in honor of the Rochester physician, Russell M. Wilder, the National Vitamin Foundation of New York reported recently. This foundation's program is designed to stimulate the training of qualified young men and women to pursue research and teaching in the science of nutrition.

Dr. Wilder, who recently retired as director of the National Institute of Arthritis and Metabolic Diseases of the National Institute of Health, is living in Rochester. Head of the Mayo Foundation's department of medicine, 1931-1950, he served during World War II also as chief of the civilian food requirements branch for the United States War Food Administration.

Candidates for the fellowship must apply in writing to the national Vitamin Foundation, 15 East 58th Street, New York 22, New York, to obtain official application forms that must be returned on or before March 15. The successful applicant will begin his work at the beginning of the academic year, September, 1954.

LECTURE ON MEDICINE AND SURGERY

Mr. August C. Krey, distinguished Professor of Medieval History, will give a lecture at the Todd Amphitheater, University of Minnesota Hospitals on Monday, April 5, 1954, at 7:30 P.M. on the subject "One Thousand Years of Medicine and Surgery, 600-1600 A.D."

Mr. Krey's special interest in the history of medicine and surgery suggests definitely that this should be a very delightful occasion. Anyone interested is invited.

DULUTH ACADEMY OF GENERAL PRACTICE

The Duluth Academy of General Practice held its first annual meeting at St. Mary's Hospital, January 28, with the following elected to office: Dr. Herbert O. Hoff, president; Dr. Ralph J. Eckman, vice president; Dr. C. H. Christensen, secretary, and Dr. Henry J. Jeronimus, representative of the Duluth chapter to the state Academy of General Practice.

HENNEPIN COUNTY MEDICAL SOCIETY

Dr. Charles A. Aling is president-elect of the Hennepin County Medical Society to succeed Dr. John Moe, October 1, 1954. Other officers elected by mail ballot and announced at the meeting held February 1 are: Dr. Willis L. Herbert, first vice president; Dr. James A. Blake, second vice president; Dr. Silas C. Andersen and Dr. Leo C. Culligan, board of directors; Dr. Charles E. Merkert and Dr. Dale H. Correa, board of censors; Dr. James F. Shandorf and Dr. Walter H. Ude, board of ethics, and Dr. Roy E. Swanson and Dr. Ude, board of trustees.

RED RIVER VALLEY MEDICAL ASSOCIATION

Dr. Alan M. McKaig, Red Lake Falls, was elected president of the Red River Valley Medical Association at the annual meeting January 8, held at Crookston. Dr. McKaig succeeds Dr. John L. Delmore, Roseau, as president. Other officers elected were Dr. Harold R. Thysell, Crookston, vice-president; Dr. R. O. Sather, Crookston, secretary-treasurer; Dr. B. R. Kinkade, Ada, Board of Censors; Dr. George Sather, Fosston, delegate to the House of Delegates, Minnesota Medical Association, with Dr. O. K. Behr, Crookston, as alternate.

CONTINUATION COURSES

The University of Minnesota will present a continuation course in *Radiology for General Physicians* May 3 to 5, 1954, under the direction of Dr. Leo G. Rigler, professor and head, Department of Radiology. Registrants for the course will spend most of their time in the University Hospital Department of Theology reading films and carrying out procedures in association with members of the faculty of that department. A minimum of didactic material will be presented. Because of the nature of this course, registration will be strictly limited. Early application is therefore suggested. Accommodations will be available in the Center for Continuation Study as usual.

The University of Minnesota will present a continuation course in *Surgery for Specialists* in that field May 6 to 8, 1954, at the Center for Continuaion Study. Emphasis will be placed on recent advances in gastrointestinal and biliary tract surgery. Guest speaker will be Dr. Warren H. Cole, professor and head, Department of Surgery, University of Illinois College of Medicine, Chicago, who will also deliver the annual E. Starr Judd Lecture on the evening of May 6. The course will be presented under the direction of Dr. Owen H. Wangensteen, professor and chairman, Department of Surgery, and the remainder of the faculty will include members of the faculty of the University of Minnesota Medical School and the Mayo Foundation.

The University of Minnesota will present a continuation course in *Electrocardiography for General Physicians* at the Center for Continuation Study May 10 to 15, 1954. Emphasis will be placed on practical experience in the interpretation of electrocardiograms. Each registrant will have an opportunity to read approximately 200 tracings under the supervision of the teaching staff. Separate sessions are being planned for those who consider themselves "beginners" in electrocardiography. The faculty for the course will consist of members of the staff of the University of Minnesota Medical School and the Mayo Foundation.

In Memoriam

SETH EDWIN GILKEY

Dr. Seth Edwin Gilkey died January 19, 1954, at St. Andrews Hospital in Minneapolis. He was sixty-eight years old.

Dr. Gilkey had practiced medicine for nearly twenty-five years at Watson, Minnesota, and in Minneapolis for several years. He was born at Dundas and attended South High school in Minneapolis and Hamline University before going to the University of Minnesota medical school from which he was graduated in 1909.

At the time of his death Dr. Gilkey was associated with the Minnesota Department of Veterans Affairs and lived at 1911 West Ramsey County Road D. He served in the United States Army Medical Corps in World War I and as an examining physician at the Farragut, Idaho, naval base in World War II. He was also medical advisor for an extended period for the Minnesota Division of Social Welfare. He was a member of the Ramsey County Medical Society, the Minnesota State Medical Association and the American Medical Association.

Surviving are his wife, the former Jean Robb of Minneapolis; a son, Seth E. Gilkey, Jr., St. Paul; his mother, Mrs. Eunice L. Gilkey, Minneapolis, and four sisters, Mrs. John Robb, Mrs. Albert Maiers, and Mrs. Anthony Pratschner, all of Minneapolis, and Mrs. Raymond Galbraith, California.

RICHARD WILLIAM MAERTZ

Dr. Richard William Maertz died at the age of thirty-three after a long illness in Faribault, January 13, 1954. He was the son of Dr. W. F. Maertz of Saint Paul and had lived in Faribault since 1950.

Dr. Maertz was born at New Prague and received his preliminary education in the New Prague schools and at St. John's University at Collegeville. He was graduated in medicine from Creighton University at Omaha in 1946 and served his internship at St. Joseph's Hospital in Saint Paul. He practiced first at Goodhue, Minnesota, before moving to Faribault. He was a member of the Rice County Medical Society, the Minnesota State Medical Association and the American Medical Association.

He is survived by his wife, the former Shirley O'Connor and six children: Richard, 8; twins David and Thomas, 7; James, 5; Mary, 3, and Elizabeth Ann, three months. Also surviving are his parents, Dr. and Mrs. Maertz, and three sisters, Mrs. Leon Cain and Mary Ruth Maertz of Saint Paul and Mrs. Robert Turner of Alexandria, Virginia.

ALBERT MILLER

Dr. Albert Miller, emeritus member of the staff of the Mayo Clinic, died at the age of eighty-six at Methodist Hospital in Rochester, February 7, 1954.

Dr. Miller was a pioneer roentgenologist. He joined the Clinic staff in 1913 as assistant to Dr. Russell D. Carman. The two men together published many papers on roentgenology, also the textbook, "The Roentgen Diagnosis of Diseases of the Alimentary Tract" in 1917. In 1923 he became a consultant in the section of roentgenology at the Clinic and in 1923 an instructor in radiology in the Mayo Foundation graduate school of the University of Minnesota. He retired from the Clinic staff in 1944.

Dr. Miller was born in Posey county in Indiana. As a young man he was interested in newspaper work and he became editor for a time of a Princeton, Indiana, newspaper. He was graduated from the University of Indiana in 1888 and from the Marion Sims-Beaumont Medical college, later the St. Louis University medical school, in 1903. He served an internship in the St. Louis City Hospital and practiced there and in East St. Louis until he went to Rochester.

His only survivor is his wife, the former Myrtle M. Richardson, of Rochester.

OLAUS LEWIS PETERSON

Dr. Olaus Lewis Peterson who practiced medicine for forty-five years at Cokato, died January 30, 1954, at the age of eighty-one.

Dr. Peterson was a leading citizen of his community for many years, having served as mayor and as a long-time member of the Board of Education as well as physician and hundreds of patients and friends attended a community celebration in his honor held at Cokato in 1949.

He was born at Collinwood Town near Cokato and received his B.A. degree from Gustavus Adolphus college. He was graduated in medicine from the University of Minnesota in 1905 and served his internship at Bethesda Hospital in St. Paul. He entered practice at Lindstrom in 1906 and practiced thereafter for short periods at Mora and Lafayette before settling permanently in Cokato.

Dr. Peterson was a member of the Wright County Medical Society, the Minnesota State Medical Association and the American Medical Association.

Surviving him are his wife, Mathilda; a son, Dr. Osler Peterson, who is associated with the Rockefeller Foundation and stationed at Chapel Hill, North Carolina; and two grandchildren.

AVERY deHART PRANGEN

Dr. Avery deHart Prangen, senior consultant in ophthalmology at the Mayo Clinic, died after a long illness at St. Mary's Hospital in Rochester January 30, 1954. He was sixty-three years old.

Dr. Prangen was born in Hornell, New York, and

(Continued on Page 240)

Woman's Auxiliary

WANTED: RECRUITS FOR THE HEALING ARTS

The following article was written by Mrs. David J. Halpern, Auxiliary member from Brewster, for *Minnesota Clubwomen,* the publication of the Minnesota Federation of Women's Clubs. This organization is doing an excellent job with a program of recruitment for allied medical careers. It was felt that this article was worthy of reprint here since doctors' wives are interested in the projects of other women's groups who are so vitally interested in medicine and related subjects. Auxiliary members are asked to write Mrs. Stanley Peterson, 510 Rockford Street, Austin, chairman of the Auxiliary's committee on allied medical careers, for informational material.

" 'I'd like to be a doctor,' says your teen-age son. Or. 'I think I'll go into nursing,' muses your high-school daughter. These are well-known professions, respected and honored. But too few young people with an interest in the healing arts know about the opportunities in other fields that are closely allied to medicine and nursing. That is one reason why there is a serious shortage of trained workers in these fields. We as clubwomen can help to meet this need by informing ourselves about these opportunities and telling our young folks about them.

"Many young people are fascinated by hospitals but know little of the variety of talents, skills, and opportunities involved in some of the jobs done there.

"*Medical technology,* for instance . . . The 'med tech' —usually a girl, though some young men do enter this profession—is the doctor's invaluable aide in performing tests for diagnosing hundreds of conditions and in determining the most effective treatments to use. Both men and women find exciting jobs in the field of *x-ray* technology—a rapidly developing field that requires a variety of highly skilled techniques. Aptitude in science and mathematics, plus an interest in medicine, are desirable in the young person looking toward either of these jobs.

"Any girl who likes to study foods and nutrition in relation to their bearing on health would do well to consider becoming a *dietitian.* Many dietitians work in hospitals, where they are responsible for planning and serving special diets prescribed by doctors for their patients. With this skill and training as a basis, the dietitian might go on to become a nutritionist and serve as consultant to many dietitians and other professional people.

"Two careers are of special interest to those who deplore the tragic waste of economic and human resources because thousands of otherwise active people are disabled by accidents or disease. Feats that seem like miracles are being performed with such people today, through the aid of *physical therapy*—treatments using hot and cold water, massage, electric currents, and various mechanical devices. As the patient by these means recovers some of the normal functions of injured or paralyzed muscles, he can improve his co-ordination, learn new skills, and discover a fresh interest in life through *occupational therapy.* Leather work, woodwork, metal work, clay modeling, weaving—these are only a few of the skills taught by the occupational therapist. Both physical and occupational therapy—especially the latter—are frequently of value in restoring sick minds as well as disabled bodies.

"There is also a career as a *medical record librarian.* A medical record is written by the physician and hospital team for every patient entering a hospital. This story of why the patient was admitted, the special examinations made to arrive at a diagnosis, the treatment given and the results of care then becomes the medical record librarian's responsibility. She uses these living accounts daily in working with physicians and hospital staff for better patient care, hospital administration, and medical research. For a boy or girl with an interest in patient care, administration and education who also has a flair for detail, the position of medical record librarian offers unlimited opportunities.

"The job of medical record librarian must not be confused with that of *medical librarian* or *hospital librarian.* These, too, offer interesting careers. Both require basic training in library science, followed by some specialization. The medical librarian works in a medical library—a library that serves chiefly physicians and members of allied professions. The hospital librarian is a specialist in a library that serves chiefly hospital patients.

"Our mental picture of a *nurse* is apt to be of a white-clad woman moving quietly and efficiently about a hospital floor. But we must remember that there are many different careers in the general field of nursing. The need for both professional and practical nurses still far exceeds the number in training, and men as well as women are needed in many branches of nursing. There is need for nurse anesthetists, for public health nurses, for nurse educators, nurses to serve as helpers in medical research and to administer hospitals, schools of nursing, and state and national programs.

"Still another field in which the number of jobs available far exceeds the supply of trained people is that of *health education.* Health educators are recruited from a surprising variety of backgrounds—teaching, nursing, and journalism being the chief. A health educator serves as consultant in educational methods and materials to schools, communities, health departments, or voluntary health agencies.

"All the professions mentioned require considerable education beyond high school. Not quite so exacting in its demands but offering an attractive career for the girl interested in both medicine and business is the job of *medical secretary.* Her work may begin with recording and transcribing reports of diagnoses and prescribed treatments, taking appointments and acting as receptionist, but many medical secretaries have gone far beyond this point. Some of them have even collaborated with doctors in preparing and publishing medical articles and books.

"In all these fields allied to medicine, the young person with ability, initiative, and a genuine liking for the healing arts can find satisfaction, security, and success. Every graduate of an accredited school can be sure of a position, not only in Minnesota but anywhere in the United States. There is a trend today toward higher salaries, shorter hours, and improved working conditions in all these professions. There are loans and scholarships available. For young people with a desire to serve, what could be more attractive than the opportunity to become a member of a team that works together to alleviate suffering, promote health, and save lives?"

RAMSEY AUXILIARY REPORTS PROJECTS

The Woman's Auxiliary to the Ramsey County Medical Society continued its regular activities during recent weeks.

Members staffed booths for the March of Dimes in January, in downtown Saint Paul stores, in Highland Village and in the Midway district. Approximately $300 was collected by the women. Mrs. R. K. Grau served as chairman.

The February board meeting, held on February 15 in the medical library of the Lowry Medical Arts Building, had good attendance. Mrs. Philip Arzt, president, presided, and doctors' wives made cancer dressings before and after the meeting.

The March meeting was held on March 22 at 12:30 p.m. at the International Institute. Foods from foreign countries were served and a short musical program followed. Members were taken on a tour of the Institute while regular classes were in progress. Program chairmen for this meeting were Mrs. L. T. Simons and Mrs. M. D. Hilker.

STEARNS-BENTON AUXILIARY

Early days of the Stearns-Benton County Medical Society Auxiliary were recalled at the November meeting of the group held at the home of the president, Mrs. L. M. Evans, Sauk Rapids.

Scrap books and minute books for the years from 1924 when the auxiliary group was organized, until 1930 were displayed and reminiscences were exchanged. A radio interview with founding members was re-enacted and the cook book which the auxiliary published in 1926 with an initial investment of $4.43 and an ultimate profit of $1,164 was especially remembered. The money went to furnish a room in the St. Cloud Hospital. Mrs. R. J. Cesnick of St. Cloud was program chairman for the event. Assisting hostesses were Mrs. S. J. Raetz of Maple Lake and Mrs. C. S. Donaldson of St. Cloud.

The January meeting of the Stearns-Benton group was held at the home of Mrs. W. B. Richards of St. Cloud with Mrs. Edward M. Anderson, St. Cloud, vice president, acting as chairman in the absence of Mrs. Evans.

Plans for a tea for the purpose of interesting high school girls in nursing as a career to be held soon at the St. Cloud Hospital, were outlined by Mrs. Gilman Goehrs of St. Cloud. A motion picture film called "St. Cloud, France," was shown through the courtesy of the St. Cloud Public Library. Mrs. C. F. Brigham, Jr. and Mrs. James P. O'Keefe, secretary of the auxiliary, and both of St. Cloud, assisted Mrs. Richards at the coffee hour which followed and which served to introduce two new members, Mrs. Robert De Weese and Mrs. L. A. Loes of St. Cloud.

THE MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

230 Lowry Medical Arts Building
Saint Paul 2, Minnesota

E. M. Jones, M.D., Secretary

OLIVIA PHYSICIAN'S LICENSE SUSPENDED FOR FIVE YEARS

In the matter of the revocation of the license of Manford B. Dahle, M.D.

The Minnesota State Board of Medical Examiners on February 13, 1954, suspended for a period of five years the medical license held by Dr. Manford B. Dahle of Olivia, Minnesota. Dr. Dahle, at a previous meeting of the Medical Board, had admitted the truth of the charges contained in a citation for the revocation of his license which was served upon him on October 21, 1953. The citation charged Dr. Dahle with a series of acts of misconduct as a physician. These acts arose at the time or immediately following the use of alcoholic liquors by Dr. Dahle. Following Dr. Dahle's appearance before the Medical Board in November, 1953, and before the case was disposed of, Dr. Dahle was arrested and entered a plea of guilty to a charge of driving while under the influence of intoxicating liquor.

Dr. Dahle was born at Eagle Bend, Minnesota, on March 2, 1912, and received his Doctor of Medicine degree from Rush Medical College on June 10, 1938. He was licensed by examination in Minnesota in the following year and practiced at Glenwood, Minnesota, prior to locating in Olivia in October, 1948.

Of General Interest

Dr. Corazon A. Manayan, a young native of the Philippines, now is a resident physician in obstetrics at St. Mary's hospital in Minneapolis. She received her medical degree from the University of Santo Tomas in Manila. She was a second lieutenant in the underground organization when the Japanese invaded the Philippines in 1942.

* * *

Dr. Hermina Hartig left for an extended trip in the South upon her retirement as chief Minneapolis school physician. She will return about April 1.

* * *

Dr. Karl Vestling, and family, left for Bremerhaven, Germany, and then will leave for Stockholm, Sweden, where he will do research in bio-chemistry at the Nobel Medical institute with Dr. Hugo Theorell of that institution. Dr. Vestling is a graduate of Carleton College in 1934.

* * *

A special alarm fire destroyed the offices of **Dr. John Williams, Dr. Robert K. Grau,** and Dr. Sherman Miller, dentist, all of Saint Paul, on February 5. Damage to the building is about $20,000 and to equipment about $25,000.

* * *

Dr. E. J. Huenekens was awarded the 1954 distinguished service certificate today by the Community Chest and Council of Hennepin County. The Minneapolis pediatrician and civic leader is the twenty-first person to receive the annual award, given in recognition of exemplary community service.

* * *

Dr. Karl S. Klica, medical director of St. Barnabas hospital for the past three years, submitted his resignation to become administrator of Presbyterian hospital in Chicago.

* * *

Dr. Lawrence C. Kolb, member of the staff of the Mayo Clinic, has been appointed director of the New York State Psychiatric Institute. He will also become professor of psychiatry and executive officer of the department of psychiatry at the Columbia university college of physicians and surgeons and director of psychiatry service at Presbyterian hospital in New York.

* * *

Dr. O. L. Norman Nelson was elected chief of staff of St. Barnabas hospital. **Dr. Robert G. Tinkham** was elected vice chairman and **Dr. Harold Buckstein** secretary-treasurer.

* * *

Dr. David F. Struxness, formerly of Alexandria, opened his new office in Glencoe on February 1.

* * *

Dr. Grafton A. Smith, fellow in surgery at the University of Minnesota, has been granted a $5,400 Damon Runyon fund fellowship to study under Dr. Owen H. Wangensteen, chief of surgery.

* * *

Dr. Grant L. Griebe, Brownton, has been elected president of the McLeod County Medical Society. Dr. Griebe succeeds **Dr. Kenneth Peterson,** Hutchinson. Dr. John Smythe, Lester Prairie, was elected secretary-treasurer.

* * *

Dr. Herman Juergens, Belle Plaine, was elected chief of staff of New Prague Community Memorial hospital. **Dr. Elmer Doherty,** New Prague, is vice president and re-elected secretary-treasurer is **Dr. Elizabeth Rieschel,** Jordan.

* * *

Dr. Erikki A. Leppo, Duluth pediatrician, was the guest speaker at the annual meeting of the International Institute. Dr. Leppo assisted in organizing the child health section of the United Nations World Health organization and has been a medical officer with WHO in the Middle and Far East.

* * *

Dr. Irvine McQuarrie, head of the University of Minnesota's pediatrics department, and **Dr. Edith L. Potter,** University medical school graduate and former staff member, are among ten doctors to be named to the 1954 honor roll of medicine by the magazine, *Modern Medicine*. Dr. McQuarrie was honored "for bettering understanding of metabolic disturbances in children," and Dr. Potter's award was for her "outstanding contributions in the field of pediatric pathology." Dr. Potter is the only woman to win the award this year.

* * *

Dr. Donn G. Mosser, instructor in radiology, University of Minnesota, has been awarded one of three American Cancer society fellowships in clinical radiation therapy for study in cancer centers in Great Britain, France and the Scandinavian countries.

* * *

Dr. David Glick, professor of physiological chemistry in the University of Minnesota medical school, will deliver two lectures in March at the Royal Caroline Medico-Surgical Institute of Sweden in Stockholm. In addition, he had been asked to lecture in the Carlsberg laboratory in Copenhagen.

* * *

Elmer S. Paulson, Saint Paul, radiologist and clinical instructor in radiology at the University of Minnesota, spoke to the Cerro Gordo County Medical Society in Mason City, Iowa, February 9, 1954, on "Radio-iodine."

* * *

Dr. Joseph Brennan, Duluth, told of his experiences as a camp physician when he was a prisoner of war of the Germans, his later escape and subsequent work in the American and British underground, at the Friday Club in Cloquet January 15. Dr. Brennan was educated at the University of Malta, Rome, Bologna, London as well as Minnesota. He is a Fellow in the Royal Society of England for his work in tropical medicine and hygiene.

* * *

Dr. Carl J. Potthoff, Minneapolis, regional medical consultant for the National Foundation for Infantile Paralysis, discussed the progress of the foundation's polio prevention program at the Mankato Lions Club meeting January 14. Dr. Potthoff has previously served as associate medical director of the American Red Cross, Washington, D. C., and an area medical officer in the Bureau of Indian Affairs at Albuquerque, New Mexico.

* * *

Dr. James H. Dokken, associated with **Dr. L. J. Hoyer**, at the Windom Clinic since July, 1953, has now become a partner. Dr. Dokken, a graduate of University of Minnesota School of Medicine, had a Fellowship at the Mount Sinai Hospital, Minneapolis, prior to his coming to Windom.

* * *

Dr. James O'Keefe, St. Cloud, has recently moved into a new nine-room clinic with facilities for offices and laboratory, plus a private parking lot to accommodate the patients.

* * *

A seventy-five-year-old painting has been hung in the lobby of the Waseca Memorial Hospital recently, in memory of the late Dr. Clifford T. Wadd, Janesville, who died in an automobile near Franklin, in 1952. The painting, selected by **Dr. and Mrs. S. C. G. Oeljen**, Waseca, is "Tranquility," a pastoral scene by the English artist, George Turner. It was purchased at the Finley galleries in Chicago from funds given in memory of Dr. Wadd.

* * *

Dr. A. M. Nielsen, Northfield, spoke of the time and expense involved in building up the medical divisions of civil defense at a recent meeting of the Business and Professional Women's meeting. Supplies needed would be expensive, Dr. Nielsen said, and also a high percentage of the medicines would deteriorate, be useless after a few months, and need replacement.

* * *

Dr. Margaret C. Anderson, Mankato, gave a talk on the topic, "Recent Advances in Anesthesia as Related to the Small General Hospital," at a meeting of the Tri-County Society January 13. The Tri-County Society includes doctors from Blue Earth, Watonwan, Brown, Sibley, Le Sueur and Nicollet counties.

* * *

Hennepin County had 455 cases of polio with seventeen deaths in 1953 which made it the hardest hit county in Minnesota. Ramsey County had 414 cases with twenty-five deaths during the year.

* * *

Dr. Carl W. Waldron, Hopkins, was appointed head of the Emergency Medical and Public Health Committee of the Minneapolis Civil Defense office January 14. Dr. Waldron succeeds **Dr. Frank J. Hill**, who recently resigned as city health commissioner.

* * *

Dr. Philip A. Olson, Grand Forks, North Dakota, and Ruth Ann Tjossem, Sioux City, Iowa, were married recently at the Mount Olivet Lutheran Church, Minneapolis. Dr. Olson attended the University of North Dakota, was graduated from the University of Illinois School of Medicine, and is completing a residency in radiology at University of Minnesota.

* * *

Duluth Health Department closed its venereal disease clinic recently after thirty-five years of operation. Dr. Mario Fischer, health director, said that the clinic, held twice a week at the Miller Memorial Hospital is no longer necessary. He said, "It is significant in that many years ago the venereal disease picture was thought to be almost insurmountable. It has now become so infrequent here that, having it treated at taxpayers' expense is not justifiable."

* * *

Dr. Mitrofan Smorszczok, a refugee from Europe, now of the Hart Hospital staff at Monticello, spoke at the Braham Area Parent-Teacher Association January 18. A practicing physician in Latvia, he came under Communist rule when that country was divided between Germans and Russians. In a so-called free election of commissar, Dr. Smorszczok found he had to vote for the Communist candidate in order to stay alive. Medical supplies were also difficult to get during his practice there.

* * *

Dr. Hermina Hartig, Minneapolis, had her last day as chief school physician of Minneapolis schools when she turned sixty-five January 13, but she is not ready to "sit down in a rocking chair and knit." "In fact, I'd first have to learn how to knit," she said recently. Born in Wahpeton, North Dakota, Hermina Simonson came to the University of Minnesota to train as a medical missionary. While at the University she met and married Dr. Hugo Hartig. Her husband was killed in an automobile accident in 1926, and, with four children, Dr. Hartig went back to her profession after taking refresher courses. In 1934 she became school physician under the city's health commissioner and in 1944 she was made head of the department.

* * *

Dr. Justus Ohage, Saint Paul, president of the Minnesota State Medical Association, is the newest member of the Minnesota Poll's Advisory Board, succeeding **Dr. O. J. Campbell** of Minneapolis.

* * *

Dr. Walter C. Alvarez, Chicago, spoke at the Minnetonka Parent-Teacher Association, Excelsior, January 12, on the topic, "What Makes Mothers Nervous." Dr. Alvarez, medical columnist, editor, and former Mayo Clinic physician, is a recognized authority on psychosomatic medicine.

Dr. Norman Johnson, Minneapolis, spoke at St. Luke's Episcopal Hospital Church, Hastings, January 20, on the subject "The Religious Approach to Psychosomatic Medicine." Dr. Johnson, son of an Episcopal bishop, has the background to speak authoritatively in the field of medicine and religion.

* * *

Dr. B. J. Grimes, superintendent of the State Hospital at St. Peter, spoke at St. James' Rotarians at a club luncheon January 12, at St. James. His theme, care for the aged, brought out the need for the older folk to stay in their own communities and be near their families and relatives. Referring to those who also need hospitalization, attention was focused on the need for a geriatric unit in connection with the Watonwan Memorial Hospital.

* * *

Dr. Albert J. Chesley, secretary and executive officer of the State Board of Health, stated recently that the board "wants to be sure of the safety and probable results" of the polio vaccine before it is used in Minnesota. A special committee has been named to make a continuing study of the vaccine in order that a decision can be reached before the polio season begins next summer.

* * *

Dr. E. S. Boone, Luverne, has moved in to his new office location which is equipped with examining suite, x-ray machine, et cetera, all newly purchased.

* * *

Dr. J. T. O'Neil, intern at St. Mary's Hospital, Duluth, addressed members of the Miller Hospital School of Nursing, January 12, at the hospital clinic.

* * *

Dr. D. P. Anderson, Austin, president of the Minnesota Division of American Cancer Society, spoke on lung cancer and the effects of smoking at a meeting held by the Austin Chamber of Commerce January 4.

* * *

Five study groups have been set up recently by the Minnesota Commission to study the problems of the aging, with John Poor of the State Department as head of the subcommittee. The following have been chosen as chairmen: **Dr. Helen Knudsen**, State Health Department, to study health, chronic illness and rehabilitation; Robert Cerny, Minneapolis architect, living arrangement; A. Merrill Anderson, director of Minnesota state employment and economic welfare, and Dr. John E. Anderson, director of University of Minnesota Institute of child welfare, education, recreation, counselling and vocation skills.

* * *

Dr. and Mrs. J. H. Leebens, formerly of Lismore, now of Minneapolis, observed their golden wedding anniversary January 17, with open house at their home. Dr. Leebens practiced medicine in the Lismore community from 1907 to 1935.

* * *

Dr. J. A. Rorem, Appleton, was reinstated as health officer of the village at the village council's meeting January 6.

* * *

Dr. Michael Danyluk, until recently associated with Dr. Hamlin Mattson and Dr. K. A. March in pathology and surgery at the Swedish Hospital in Minneapolis, has joined Dr. March in his practice at Cambridge. Dr. Danyluk studied medicine at the University of Munich in Germany. He came to Minneapolis in 1950.

* * *

Dr. and Mrs. R. E. Billings, Franklin, were hosts to the Renville County Medical Association and its Auxiliary at their home recently. A pot-luck supper was served to the twenty-eight guests attending.

* * *

In the first edition of a publication, "Leaders in American Science," recently issued in Nashville, Tennessee, several Mayo Clinic staff men were listed. They are as follows: **Drs. Joseph McDonald, William H. Feldman, Frank C. Mann, J. Grafton Love,** and **J. A. Bargen** of Rochester, and **Benjamin T. Terry,** Tacoma, Washington, formerly of the Clinic.

* * *

Dr. G. F. Engstrom, Belgrade, is temporarily filling the position as physician in charge of medical-surgical emergencies at the Moose Lake State Hospital. Dr. Engstrom has recently completed four months of medical work at the University of Minnesota and University Hospital.

* * *

Dr. James H. Kelly, associated with the Davis Clinic, Wadena, for the past three and a half years, has affiliated with his brother, **Dr. Robert Kelly** in the Itasca Clinic in Nashwauk.

* * *

Dr. W. H. Valentine, Tracy, president of the Lyon County Tuberculosis and Health Association, stated recently that the county-wide tuberculin testing for all ages has received state and nationwide attention. More than $6,800 in county Christmas Seal funds financed the testing program with 13,667 persons having been tested. Of these, 20 per cent had tuberculosis germs, while 30 per cent of the adults are reactors.

* * *

Dr. Harold Williamson, Fairmont, spoke on the need and usefulness of clinics at the Lions Club in Fairmont, January 11. "Group practice means better working conditions and better prepared doctors," he said.

* * *

The Minneapolis War Memorial Blood Bank has increased its services to local and Upper Midwest residents. Last year a total of 20,560 units of blood were handled by the bank making a 12 per cent increase over the year before.

* * *

First Lieutenant John Rutledge, son of **Dr. and Mrs. L. H. Rutledge** of Detroit Lakes, serving in the medical corps of the army, has been given a forty-five day assignment in Raykjavik, Iceland. Lt. Rutledge, stationed at Westover Field, Chicopee Falls, Massachusetts, will serve as flight surgeon on this assignment.

* * *

The medical staff at the Lutheran Hospital at Bemidji were hosts to the pharmacists of Bemidji and surrounding villages January 20. Problems common to the professions, such as control of prescription refills, wider use of standard drugs, measures to minimize self diagnosis and self medication in the presence of serious symptoms and control of drug addiction were discussed. Henry Moen, a pharmacist and executive secretary of the Minnesota Pharmaceutical Association, was the principal speaker. **Dr. Daniel F. McCann** paid tribute to the silent service the pharmacist performs in checking and preparing prescriptions.

* * *

Dr. Lloyd C. Gilman, who has been on leave of absence from his practice at Willmar while doing special work in the field of surgery at the Jackson Clinic, Madison, Wisconsin, returned to his office in January.

* * *

A University of Minnesota Research Director and other heart specialists left January 8, for Italy where they will study the connection between the small incidence of heart disease in that country and the Italian diet. "We noted some peculiarities of blood chemistry there before and now we want to explore further the relation of diet and heart disease," said **Dr. Ancel Keys,** member of the party and director of the University's laboratory of physiological hygiene.

* * *

Mount Sinai Hospital, Minneapolis, has started construction of a $100,000 animal research laboratory near the hospital. There will be a large operating and sterilizer room, isotope laboratory, food preparation area, post-mortem room, preparation and recovery room. There will also be separate quarters for dogs, mice, guinea pigs, rabbits, and other animals used for medical research. The unit will be known as the Jay Phillips Research Laboratory, in honor of the first and present president of the Hospital Association.

* * *

Dr. A. J. Floersch, a graduate of Creighton University Medical School, Omaha, Nebraska, opened his office for practicing medicine at Glencoe, February 1. Dr. Floersch took his internship at St. Mary's Hospital, Minneapolis, served in the armed forces two years, and had a year's surgical residency at Northwestern Hospital, Minneapolis, before coming to Glencoe.

* * *

Dr. J. J. Heimark and **Dr. R. L. Parsons** have dissolved their partnership at Monterey. Dr. Heimark is returning to Fairmont to his former office to practice medicine, and Dr. Parsons will, after a vacation, open an office either in Fairmont or elsewhere. Dr. Vincent Ryding, at present resident surgeon at Northwestern Hospital, Minneapolis, will open his office in Monterey July 1, when his residency is completed.

* * *

Dr. B. J. Cronwell, Austin, left for a week of postgraduate work in electrocardiography. The course was offered by Emory University.

* * *

Dr. Lewis Hanson, Frost, was elected chairman of the Faribault county public health nursing advisory board. **Dr. A. B. Peterson,** Wells, was elected vice chairman and Mrs. Carl Hawkins, secretary-treasurer.

* * *

Dr. Frederick A. Figi, Mayo Clinic, Department of Plastic Surgery, will speak on the subject "Cancer and Chemodectoma of the Middle Ear and Mastoid," at the meeting of the American Medical Association in San Francisco, June 21-25.

* * *

Dr. C. M. Smith, Duluth, was installed as chief of staff of St. Luke's hospital for 1954. The chief elect for 1955 is **Dr. M. F. Fellows. Dr. Ralph J. Eckman** was re-elected secretary. New executive members are **Dr. D. W. Wheeler,** chief of medicine; **Dr. P. N. Bray,** chief of obstetrics; **Dr. William Swedberg,** chief of orthopedics; **Dr. Gordon Strewler,** chief of neuropsychiatry; **Dr. L. L. Merrian,** chief of infirmary service, and **Dr. H. O. Hoff,** chief of general practice.

* * *

Dr. Albert J. Chesley, Saint Paul, **Dr. William Benedict,** and **Dr. Charles Sheard,** Rochester, have been re-elected to three-year terms on the board of directors of the National Society for the Prevention of Blindness.

* * *

Dr. C. H. Sherman, Bayport, was appointed physician and surgeon of the state prison. He succeeds **Dr. E. M. Jones,** Bayport.

* * *

Dr. and Mrs. P. H. Macfarlane were aboard the luxury liner SS Lurine for an extended visit in Hawaii. Dr. Macfarlane is associated with the Mesaba Clinic and the Chisholm Memorial Hospital.

* * *

Dr. Philip Hench attended the regional meeting of the American College of Physicians in Colorado Springs, Colorado. He presented a paper "The Cortisones and Corticotropins in Rheumatoid Arthritis."

* * *

Dr. Henry Reif was elected president of the Stearns-Benton Medical society, to serve in 1955. **Dr. John Kelly,** Cold Spring, will serve as head of the group during 1954. Other officers elected for 1954 were **Dr. William Autrey,** vice president and **Dr. E. M. Anderson,** secretary.

* * *

Dr. D. V. Boardman was elected president of the Winona County Medical Association. **Dr. Pat Rol-**

lins was re-elected treasurer and **Dr. W. O. Finkelnburg** was re-named secretary.

* * *

Dr. Thomas J. Kenyon has been named president of the medical staff of St. Joseph's Hospital. Other new officers are **Dr. J. P. Medelman,** vice president, **Dr. Richard W. Leick,** secretary, and **Dr. Bernard O'Reilley,** treasurer.

* * *

Dr. Kristofer Hagen, who has for some time, been associated with Dr. Theodore Greenfield at Cokato, Minn., has now opened his own office at the Hub Medical Center, 34 W. 66th Street, Richfield, Minnesota. Dr. Hagen returned from India in 1952, after six years' service under the Santal Mission in charge of a mission hospital at Mohulpahari, Santal Parganas, Bihar.

* * *

HOSPITAL NEWS

At a recent election at Asbury Methodist Hospital, Minneapolis, members of the medical staff were elected as follows: Dr. Paul J. Preston, chief-of-staff; Dr. Robert B. Potter, vice president, and Dr. Charles D. Adkins, secretary-treasurer. Members of the advisory board together with the officers are: Dr. R. C. Webb, surgery; Dr. George E. Hudson, maternity; Dr. Wayne S. Hagen, medicine; Dr. Alice K. Brill, pediatrics, and Dr. P. C. Petersen, general practice.

* * *

Dr. Olga Hansen-Litzenberg has been re-elected chief of Eitel Hospital medical staff. Dr. G. T. Schimelpfenig, is assistant chief, and Dr. O. L. Zahrendt is secretary-treasurer.

* * *

The Minneapolis Hospital Council held elections at their annual meeting January 21 with the following officers elected: Dr. Benjamin W. Mandelstam, administrator of Mount Sinai Hospital, president; Kenneth J. Holmquist, superintendent of Minneapolis General Hospital, vice president; Vernon Spry, administrator of Asbury Methodist Hospital, secretary, and Carl N. Platou, administrator of Fairview Hospital, treasurer. As president Dr. Mandelstam succeeds Dr. Karl S. Klicka, administrator of St. Barnabas Hospital.

* * *

Dr. F. G. Chermak, International Falls, has been elected chief of staff of Falls Memorial Hospital recently. Dr. Chermak was formerly associated with the Webber Clinic in Duluth and the Hibbing General Hospital.

* * *

Dr. J. F. Zagaria, formerly of Wausau, Wisconsin, has been named chief anesthesiologist of St. John's Hospital, St. Paul. Mrs. Mary Anna Anderson has been named chief pharmacist and Miss Virginia Reid, head dietitian.

* * *

The medical staff of St. Ansgars Hospital, Moorhead, elected Dr. V. J. Carlson, president; Dr. O. H. Johnson, vice president, and Dr. Carl Simison, secretary-treasurer. The president and secretary-treasurer together with Dr. H. G. Rice and Dr. J. W. Duncan, will compose the executive committee.

Formal organization of the Twin City Hospital Association by the Minneapolis and St. Paul Hospital Councils has been complete. Donald Wood, executive secretary, will be located in the Minnesota Hospital Service Association (Blue Cross) Building, 2610 University Avenue, St. Paul.

* * *

Dr. Bernard I. Saliterman succeeded Dr. Max Seham as chief of staff of Mount Sinai Hospital, Minneapolis, recently. Dr. Meyer Z. Goldner, was elected vice president; Dr. Ephraim B. Cohen, secretary-treasurer. Department chiefs are: Dr. Robert A. Green, medicine; Dr. David Gaviser, surgery, and Dr. Maxwell M. Barr, obstetrics-gynecology. The executive committee is comprised of the officers, department chiefs, and Dr. Sidney Scherling, Dr. Julius Feinstein, and Dr. Max Seham.

* * *

Miller Memorial Hospital, Duluth, held elections for the medical staff January 8. Dr. A. C. Kelly was elected chief-of-staff; Dr. F. T. Becker, vice chief of staff; Dr. John Schmid, secretary-treasurer, and Dr. J. C. Feuling and Dr. J. J. Dwyer, executive committee members.

* * *

Officers of the Abbott Hospital's medical staff is as follows: Dr. John Haugen, president; Dr. O. J. Campbell, vice president; Dr. Walter Hoffman, secretary; Dr. John Tobin, Dr. John Pewters and Dr. John Boehrer, members of the executive committee.

* * *

The Fairmont Hospital board at a meeting recently offered to meet the trustees of Tri-Mont Hospital, hospitals located in Martin County, to work out proposals to submit to the county commissioners that would be satisfactory and helpful to both hospitals. Fairmont Hospital, forty-six beds, is in dire need of enlargement and added facilities, and is seeking an allotment of county funds to meet the extra expenditures. Citizens of the Triumph-Monterey area feel that they should not be asked to support through taxes another hospital when they have their own, built a few years ago at a cost of $150,000.

Dr. Helen Knudsen, State Chief of Section of Hospital Service, and Dr. Robert N. Barr, deputy executive officer of the State Board of Health, spoke to the group concerning these problems.

* * *

Facing the need of enlargement both in space and facilities of the St. Mary's Hospital of Duluth, the administration is getting under way in the fund-raising campaign. G. E. Andreson, Chairman of the St. Mary's Hospital Building Fund campaign, has appointed R. P. Buckley, M.D., chairman of the Medical Division of the campaign. F. T. Becker, M.D., and E. D. Bettenhausen, D.D.S., will assist him as vice chairmen in organizing solicitations among doctors and dentists of Duluth.

* * *

Dr. O. J. Seifert, New Ulm, was elected president of the Loretto Hospital at the annual staff meeting January 19, with Dr. Rolf Hovde, Winthrop, as vice president, and Dr. Howard A. Vogel, secretary. Dr. C. A. Saffert is the retiring president.

At the annual staff meeting of the Union Hospital January 19, the following were elected: Dr. Howard A. Vogel, president; Dr. Albert Fritsche, vice president, and Dr. Rolf Hovde, Winthrop, secretary. Dr. Vogel succeeds Dr. William Black as president.

MINNESOTA BLUE CROSS-BLUE SHIELD

In the year 1953, payments to doctors for services rendered to Blue Shield subscribers totaled $4,247,000. This amount marks a new high in annual amount of money paid to doctors as well as an increased percentage of the amount paid by the subscriber returned to him in the form of medical care benefits. While the dollar volume of claim payments in 1953 has increased 15 per cent over 1952, the amount paid out in 1953 represents approximately 50 per cent of the total amount paid out for claims in the preceding three years. Further analysis shows that the payments in 1953 are 88 per cent greater than the amounts paid in 1950. With the constant increase noted each year, and with the increased benefits in the contract effective January 1, 1954, Blue Shield payments to doctors of medicine for services rendered Blue Shield subscribers should approach the $5,000,000 mark in 1954.

Other interesting facts in the growth of Blue Shield claims payments are the great number of claims received and processed during the year with no increase in the number of personnel employed. Through a four-year period, while the dollar volume of benefits has increased 88 per cent, the number of claims received has increased over 100 per cent. However, the number of persons employed by Blue Shield has increased only 20 per cent since 1950, and for almost two years has remained constant. Where in 1952, an average of about 10,000 claims was processed each month, in 1953 this increased to an average of 11,500 or an increase of 15 per cent. Yet with this increase, no additional personnel was necessary. Again in 1953, as in 1952, the assimilation of an increased work-load reflects progress in internal procedures which permits of an efficient operation and a reduction in the cost of claims processing.

Another interesting element in the ability of the personnel to assume an additional work-load is evident by a reallocation of the correspondence received. While in 1952, six persons were involved in handling the various types of correspondence, with the increased number of claims and growth of Blue Shield, reorganization of work-loads and personnel has avoided the need to increase the number of personnel in this particular unit.

Internal reorganization of the Blue Shield Claims Department also provides more time to disseminate information to members of the medical profession and to improve relations with doctors. More time has been available for providing more information about the Blue Shield contract and the Blue Shield procedures, both of which result in greater efficiency in the doctor's office and in Blue Shield. In this particular field, many of the problems which have formerly existed were eliminated through the professional relations activities in 1953. The program of professional relations is continuing and is being increased as rapidly as possible. It is intended that continued progress will be made in this field and that greater contact can be made with those persons in the doctor's office in order to eliminate many of the problems confronting them.

During the month of December, 10,376 participant subscribers were enrolled in Blue Cross bringing the net enrollment as of December 31, 1953, to 986,885 Blue Cross participant subscribers.

Hospitalization expense incurred for subscribers for the month of December, 1953, reached the all time high point of $1,471,749.53, bringing the total amount paid for the care of subscribers during 1953 to $15,134,121.69. In comparison with the figures of 1952 to date, over $2,587,665.46 more was paid for the care of subscribers during 1953.

At the same time, even though hospital costs were at an all time high, Blue Cross reduced its overhead expense to an all time low of 6.8 per cent of income compared with 7.7 per cent of income during 1952.

Mr. A. M. Calvin, president of Blue Cross, said that operational improvements, as a result of a competent staff, have helped to reduce operational costs. Hospitalization has shown a decided increase with one out of every six Blue Cross participant subscribers hospitalized last year. The co-operation of the public, the hospitals, and the medical profession is needed to determine whether or not the hospitalization of all persons was for necessary hospital care.

One out of every three persons in Minnesota is now enrolled in Blue Cross and this figure exceeds that of the nation as a whole which has every fourth person enrolled.

IN MEMORIAM

Avery deHart Prangen

(Continued from Page 232)

received a B.S. degree in 1913 and an M.D. degree in 1916 at the University of Michigan. He served his internship at the University of Michigan hospital and became an instructor there in 1917. He joined the Mayo Clinic staff as an assistant in ophthalmology in 1918 and continued with the Clinic for thirty-five years until his retirement because of illness in 1952. He served also as associate professor of ophthalmology in the Mayo Foundation.

He was a member of the Minnesota Academy of Ophthalmology and Otolaryngology, the American Academy of Ophthalmology and Otolaryngology, the American Ophthalmological Society, Alpha Kappa Kappa and Sigma Xi. He held membership, also, in the Olmsted-Houston-Fillmore-Dodge County Medical Society, the Minnesota State Medical Association and the American Medical Association. Until his retirement Dr. Prangen had been chairman for four years of the National Interprofessional Committee on Eye Care and he was the first to hold the post. He was a member of the Rochester Kiwanis club and president in 1926.

Surviving are his wife, the former Alice Conley, a daughter, Mrs. David Judd of Eugene, Oregon, and a son, William, of Minneapolis.

BOOK REVIEWS

Books listed here become the property of the Ramsey, Hennepin and St. Louis County Medical Libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

THE PEPTIC ULCER INDIVIDUAL. Gerdt Wretmark. 183 pages. Illus. Price 20 Swedish Crowns, paper cover. Copenhagen, Denmark: Ejnar Munksgaard, 1953.

SCHOOL HEALTH SERVICES: A report of the Joint Committee on Health Problems in Education of the National Education Association and the American Medical Association. Charles C. Wilson, M.D., Professor of Education and Public Health, Yale University, Editor. Illus. Price $5.00. Washington: National Education Association of the United States, 1201 Sixteenth Street N.W. or Chicago: American Medical Association, 535 North Dearborn Street, 1953.

This is a comprehensive and highly useful book for anybody who has any responsibility for the care of children, but especially for teachers, nurses and school physicians.

It is happily free from the high-flown educator's shop-talk which occasionally plagues the uninitiated reader. And many for whom the book will be useful are not initiated into these technical mysteries.

Since it is sponsored jointly by the National Education Association and the American Medical Association, it steers a sure course through the sometimes ruffled waters of division of responsibility for the care of children between the school, the parent and the family physician. Also it provides an excellent, up-to-date compendium of information on child health, including a valuable section on all the health problems connected with physical education, school athletics, and school camps.

Each chapter and section was prepared by experts in their fields and the whole has been assembled with a wealth of illustrative material, sample forms, lists of supplies, studies and graphs to serve as a handy manual, as well as a statement of sound principles underlying a school health program.

Many a school administrator has been waiting for a practical book like this, but parents, as well as teachers, could profit by reading it and keeping it handy.

MANAGING YOUR CORONARY. By William A. Brams, M.D., 158 pages. Illus. Price $2.95, cloth. Philadelphia: J. B. Lippincott Co., 1953.

Explaining science to the general reader is a responsibility not always accepted by physicians. Dr. Brams is well equipped to help patients understand the heart, and its most common affliction, and discharges his appointed task. I found little to object to and would recommend it to patients who are interested in their condition. The patient with "the head in the sand" attitude toward his illness would not be benefited by such a discussion.

The critical would not accept the thesis that coronary disease is more common in the "executive class" or that worry and modern life's tension necessarily are causative. The drawings of the heart and its vessels (Figs. 2 and 3) are anything but clear. Figure 4 is not labeled as a microscopic detailed drawing. On page 44, there is a reference to "the ST wave," apparently a new electrocardiographic term. On page 96, it is stated "the commonest complication after an attack of coronary thrombosis is embolism . . ."; this would be unacceptable to many workers in the field.

But these are minor points. The book is for patients and it is informative and readable. The philosophy expressed in the dedication deserves emphasis.

W.B.M.

SYNOPSIS OF PEDIATRICS. By John Zahorsky, M.D., and T. S. Zahorsky, M.D. Sixth edition. 470 pages. Illus. Price $7.50. St. Louis: C. V. Mosby Co., 1953.

This book covers the whole field of pediatrics in condensed form in its 470 pages. It is amazing how much information on children's diseases the authors have been able to include in this handbook of fairly small size. The most important technical procedures in diagnosis and treatment have been intelligently selected and discussed with authority. Especially valuable are many important personal observations and advice on pediatric practice in the patient's home and in the doctor's office. The book is well illustrated with many vivid photographs, tables and graphs.

The authors have tried to keep the book up to date as much as possible. Probably the text could be made still more concise by omitting some obsolete treatment methods (e.g. for syphilis), which now have mainly historical significance, and present only modern methods. The book is printed with small print which might be a handicap for readers with impaired vision. A larger print in future editions would be an asset.

The authors have written this book especially for the use of medical students to give them in a concise form all the important aspects of various pediatric problems. The book is particularly helpful for examinations and quick references; larger pediatric textbooks should be consulted for detailed references.

This book can be recommended also to general practitioners because the authors give excellent advice on many practical questions encountered in pediatric practice and cover all the essential points in the diagnosis and treatment of various diseases of infants and children.

N. E. A. Leppo, M.D.

SURGERY OF THE BILIARY TRACT, PANCREAS AND SPLEEN. Charles B. Puestow, M.D., Ph.D. (Surg.) Clinical Professor of Surgery, College of Medicine and Graduate College, University of Illinois: Attending Surgeon, University of Illinois Research and Educational Hospitals; Chief of Surgical Service, Veterans Administration Hospital, Hines, Illinois; Chief Surgeon, Henrotin Hospital, Chicago. 370 pages. Illus. Price $9.00, cloth. Chicago: Year Book Publishers, 1953.

This handbook of operative surgery is a well-written, easily read and understood book which contains many excellent and properly placed illustrations. Throughout the book, all illustrations have the explanatory notes placed on the page opposite the illustration making for easy access to them.

The book is divided into four main sections:

I. The Liver
II. Extrahepatic Biliary System
III. The Pancreas
IV. The Spleen

Each of these is subdivided into Anatomy and Physiology, Surgical Conditions, Differential Diagnosis and Surgical Techniques. Preoperative and postoperative care, as well as types of anesthesia, are well covered.

This book, as stated in the preface, is not intended for the untrained or inexperienced physician who might wish to perform operations for which he is not adequately prepared, but offers a wealth of material for one who is obtaining such training or experience under adequate supervision. It is also an excellent review and refresher course for a busy older surgeon who may find it difficult to keep up with all the vast amount of literature.

N. E. Tosseland, M.D.

ARSENIC POISONING

(Continued from Page 210)

mucous membranes and are stored in the liver, kidney, walls of the gastrointestinal tract, the spleen and lungs. Deposition in the hair and bones starts within two weeks and stays fixed for years. It is excreted in the urine and feces, within two to eight hours and up to seventy days after repeated administration.[1-3]

While several case reports on the use of this medication in allergy with toxic results have appeared, it is evident that many more must go unrecognized.[4,5,6] This case further well illustrates the medical dictum that all that wheezes, and sneezes and itches is not allergy, not even in the allergic patient; and that potent medication should be prescribed only under constant and rigid supervision.

NUMBERS SYSTEM

How many times have you been at a baseball game or a movie when a physician is called away for an emergency? To allow discreet paging of doctors at large gatherings and eliminate any unnecessary embarrassment on the doctor's part, the Medical Society of Milwaukee County has activated a new system. Each member has been assigned a numbered card which is to be used by members of his family, his hospital, the Medical Society Physicians' Service or his office when it is necessary to page him while he is in a public place or at a public gathering.

"Instead of 'Dr. Smith, please call your office,' you will soon hear 'Dr. 464, please call your office,'" writes Dr. Robert S. Irwin, Milwaukee County president in the *Milwaukee Medical Times*. He feels that all society members will welcome the new system.

CANCER DETECTION

A Report from the Cancer Detection Center, University of Minnesota

CLAUDE R. HITCHCOCK, M.D., and J. BRADLEY AUST, M.D.
Minneapolis, Minnesota

THE GOAL of the Minnesota Cancer Detection Center has been to develop a workable and accurate method of cancer examination including all internal organs as well as readily accessible external organs. Until a simple serodiagnostic or biologic test is available, such an effort is the only available means of detecting malignant disease in its early stages.

"Cancer Detection" implies the process of finding malignancies before symptoms or signs herald their presence, in addition to the diagnosis of precancerous conditions. Through the application of a well conceived routine plan of examination in doctors' offices, we believe several types of serious malignancy can be identified in advance of their usual signs and symptoms. More important than this, the 24 per cent of our population over the age of forty-five years who harbor a precancerous condition can be alerted for close observation or therapy.

During the five years from March 1, 1948, to February 28, 1953, cancer detection examinations have been performed on 5,352 men and women. Ninety-one cancers have been discovered at the Detection Center, and proved with biopsy or surgery. Treatment has been under the direction of the patient's personal physicians. Furthermore, a total of 1300 lesions considered to be precancerous have been detected and reported; an incidence of twenty-four per one hundred people examined over forty-five years of age. Table I demonstrates the ratio of new patient examinations and the incidence of malignancies and precancerous lesions found.

TABLE I.

	Male	Female
New Patients	2665	2687
Recheck Exams	3005	2986

Total Examinations	11,343
Total Patient's Examined	5,352
Cancer Incidence	17 per 1000 patients examined (1.7%) 7.9 per 1000 examinations performed
Precancerous Lesions	1300 (24%)

In order to facilitate the study and assure maximum cancer case finding a lower age limit of forty-five years was established. Recently the lower age limit for males has been raised to fifty years. The high incidence of carcinoma of the cervix in women in the fifth decade indicated the advisability of maintaining the lower age limit for females at forty-five years.

It is obvious that all people have *some* symptoms during any given interval of time. We have not been able to fulfill the original concept of obtaining a group of completely asymptomatic examinees for cancer detection observation. Therefore, our examinees with malignant disease have been separated into symptomatic and asymptomatic cases in reference to the particular organ or organ system in which the malignancy was found. In the group of ninety-one patients found to have cancer, forty-six patients had no symptoms referable to the organ or organ system in which the malignancy was detected and forty-five

patients had symptoms referable to the organ or organ system involved. It will be shown later that survival figures are significantly better in the asymptomatic group. Table II demonstrates the value of the recheck examination in detecting asymptomatic cancers.

Table III portrays the cancers found in the first five years of operation, according to site and relationship to symptoms.

Method of Examination

Principles of completeness and economy have been important considerations in developing the pattern of the examination. Laboratory procedures have been reduced to bare essentials, requiring only a minimum amount of technical assistance.

A detailed history form is completed by the patient prior to his visit to the Center. The patient brings a urine and stool specimen (collected after three days on meat free diet) the morning of the examination. A routine urinalysis is performed (urine sugar, albumin, microscopic for cells if urine is positive for albumin). A benzidine test on the urine has been tried, but is not as accurate as microscopic cell study to detect occult urinary bleeding. The stool is examined for occult blood with the Guaiac and Benzidine test. Routine examination of the blood includes hemoglobin determination, white blood cell count, differential count and cell morphology.

Every patient has a Levine tube passed for gastric analysis using one dose of histamine (0.5 mgm.) as stimulant. The standard sodium hydroxide and Toepfer's reagent determination for free HCl has proved most satisfactory. The Quininium ion urinary excretion test has been tried and proved too time consuming in the laboratory for large numbers of determinations daily.

Chest x-rays are taken on each patient. Suspicious lesions or single nodules are further investigated with planigrams of the involved area. Sputum is studied for malignant cells by the Papanicolaou method. If no diagnosis is forthcoming, bronchograms, bronchial washings, and bronchial biopsy (if possible) are recommended.

All patients come to the Center prepared with enemas for a proctosigmoidoscopic examination. The scope is passed to the 25 cm. level, unless peculiar conformity of the bowel (acute angulation) or stricture prevents passage of the instrument. The following conditions are checked for: (1) small adenomas (2-3 millimeters); (2) polyps (sessile or pedunculated); (3) character of the mucosa (bleeds easily, inflamed, small ulcerations); (4) diverticula, diverticulitis; (5) hemorrhoids, fissures, fistulas; (6) frank ulcerating carcinomas or intramural tumors. Excision biopsy and fulguration is recommended for all small adenomas and polyps. During the digital examination of the rectum, the prostate is palpated for hypertrophy or nodules.

All women receive a pelvic examination including bimanual palpation of adnexal areas, and direct visual inspection of the vaginal vault and cervix. Any adnexal mass is considered suspicious in this age group, and pelvic laparotomy advised. Suspicious findings in the cervix includes: (1) rough area on lip of cervix; (2) polyps; (3) blood at the os, not menstruating); (4) atrophic cervical mucosa; (5) erosion of the cervix; (6) cervicitis.

Papanicolaou smears are made of vaginal secretions and scrapings of the cervix. Suspicious areas are biopsied. Positive Papanicolaou smears must be confirmed later by positive biopsy. Suspicious (Class III) smears, in an otherwise normal vagina, indicate need for repeated cytologic examination every six weeks until smears are negative or biopsy proves the presence of a carcinoma.

After the laboratory work has been completed and the proctoscopic and pelvic examinations performed, a clinician examines the patient for the remaining problems:

1. Nose and throat with visual inspection of nasal cavity, oral cavity, and auditory canal. Inspection of the nasal pharynx and larynx with laryngeal mirror. Palpation of the neck and submandibular area for palpable lymph nodes. The thyroid gland is palpated for adenomas or masses.
2. Skin (senile keratoses, and pigmented nevi in areas of irritation are classified as suspicious). Any recently darkening or enlarging nevus is considered suspect for malignant melanoma.
3. Adenopathy is searched for in supraclavicular, axillary, and inguinal areas. The chest x-ray will detect mediastinal adenopathy.
4. Breasts are examined by inspection and palpation in both the sitting and supine position.
5. Abdominal palpation is important for detection of renal masses. Liver, spleen, gall bladder, enlarged lymph nodes, or any other masses are carefully checked.
6. External genitalia of the males are examined to include palpation of testes.
7. Peripheral muscle tissue and skeletal system are examined for deformities or lesions.
8. Brief neurological examination for possible manifestations of cerebral neoplasms.

Criteria for Special X-Ray Studies

While summarizing the results of examination, the clinician determines whether further x-ray studies are needed according to the following plan.

Gastric Intestinal Series X-Rays are Ordered for:

1. Patients with histamine achlorhydria and hypochlorhydria (less than 30° free acid).
2. Patients with occult blood in the stool.
3. Patients with strong family history of gastric carcinoma.
4. Patients with unexplained hemoglobin level below 11 grams.
5. Patients with vague symptoms of gastric pathology which in any sense could be interpreted as being due to gastric carcinoma by the examining physician.
6. Any evidence of undue weight loss.

The air contrast technique is helpful in cases of suspected gastric polyps or small mucosal defects.

Barium Enema Colon X-Rays are Indicated for:

1. Patients with abnormal findings on proctoscopic examination.
2. Patients with occult blood in the stool.
3. Patients with unexplained hemoglobin level below 11 grams.
4. Patients with a family history of large bowel malignancy.
5. Patients who have vague symptoms that could possibly be due to malignancy of the large bowel as determined by the examining physician.
6. Any evidence of undue weight loss (10 pounds or more).

TABLE IV.
COMPARISON OF GASTRIC CANCER PATIENTS

	Asymptomatic	Symptomatic
Total Number	6	5
Achlorhydria	6	5
Occult Blood	1	1
X-Ray Diagnosis (1st Visit)	1	2
X-Ray Diagnosis (Subsequent Visits)	5	3
Scirrhous	1	3
Polypoid	5	1
Ulcerating	0	1
Positive Lymph Nodes	1	4
Alive	3 (1½, 3, 5 yrs.)	1 (1½ yr.)
Deceased	3 (1¼, 1/12, 1 yr.)	4 (1/12, ⅓, ½, 1 yr.)

*Survivals are considered as of December 31, 1953.

In addition to routine barium enema x-rays, all patients found to have polyps on proctoscopic exam are given air contrast barium enema studies.

Intravenous Pyelogram X-Rays are Ordered for Patients with:

1. Blood in the urine.
2. Costovertebral pain or tenderness.
3. Palpable mass in region of kidney.

Results of Five Years' Operation

Esophagus and Stomach.—Eleven gastric carcinomas have been found, seven in males and four in females. All patients had achlorhydria and would have been been picked up by x-ray performed on this basis alone exclusive of other indications for performance of a G.I. series. In only two cases (with symptoms) was the hemoglobin below 11.0 grams. Occult blood was present in the stool of only one asymptomatic patient and one patient with symptoms. Table III demonstrates that in six patients the gastric cancers gave no symptoms, while in five patients symptoms were present.

Polypoid type carcinomas were found in *five* of the *six asymptomatic* patients and scirrhous carcinoma in one patient. In the *five* gastric cancer patients with symptoms, *four* had scirrhous carcinoma, and only one had a polypoid lesion. Table IV demonstrates the results of early diagnosis (asymptomatic patients) compared with late diagnosis (symptomatic patients) in the gastric cancer group. Three of the patients are living and well up to five years in the asymptomatic group. There is only one survivor in the group of patients with symptoms at time of diagnosis.

Early polypoid lesions have a good chance for cure with subtotal gastrectomy. Since virtually 100

TABLE V. RECTAL AND COLON CANCERS

	Asymptomatic	Symptomatic
Total Number	13	5
Diagnosed first visit	11	5
Occult blood	2	3
Hemoglobin below 12.5	0	1
Proctology positive	10	4
Barium enema	3+ (also 7 of 10 procto pos.)	3+ (also 2 of 4 procto pos.)
Ulcerating cancer	2	4
Polypoid cancer	11	1
Lymph nodes positive	2	3
Alive	11 (2⅙, 2½, 4, 3⅓, 4¾, 2¾, 1¾, 3¼, 5¼, 4¾, 4¾ yrs.)	1 (2¾ yrs.)
Deceased	2 (1⅔, 2 years after CVA)	4 (1/12, 7/12, 1⅙, 2½)

*Survivals are considered as of December 31, 1953.

per cent of polyp-bearing stomachs are achlorhydric, the gastric analysis seems to be a satisfactory method for indicating those patients with a likelihood for polyps. Polyps greater than 2 cm. in diameter have a 50 per cent chance of being malignant when found. Of those 1 cm. or less in diameter when detected about 11 per cent are malignant.

For early asymptomatic gastric cancers the most significant criterion indicating need for gastrointestinal series x-rays is achlorhydria. We do not know of a stomach cancer that has been found during this five years among the three-fourths of our patients who have normal gastric acidity.

One examinee presented during the first six months of operation of the Center with total obstruction of the esophagus due to known esophageal carcinoma. He was too ill to undergo the examination and is not counted in the series of cancers picked up in the Center. This was the only esophageal cancer seen during the first five years of function of this Center.

Colon and Rectum.—Eighteen cases of cancer of the rectum and colon have been detected: Ten in males and eight in females. Fourteen of the lesions (77 per cent) were within reach of the sigmoidoscope. Thirteen of these fourteen were in the 9 cm. to 16 cm. level. Three lesions were in the ascending colon or cecum and one was in the descending colon.

Of the eighteen patients, thirteen were free of symptoms for G.I. tract disease and five had symptoms referable to the G.I. tract. Only two of the thirteen asymptomatic patients had occult blood in the stool; three of the patients with symptoms had occult blood. Here again, for early lesions still not causing symptoms, the stool occult blood determination is not a satisfactory single screening device for indicating necessity of x-ray examination.

Routine examination of the rectum and sigmoid through the sigmoidoscope has proved to be the most useful screening device for large bowel lesions. Table V compares the colon and rectal cancers with and without symptoms. Of the group of thirteen symptom-free patients, eleven are living and well up to five years (seven over three years). Only one of the five patients who had symptoms referable to the colon at the time of diagnosis is living and well (two and three-fourths years).

There is no etiologic relationship between diverticulitis and carcinoma of the colon. However, inflammatory strictures due to diverticulitis often cannot be differentiated from constricting adenocarcinoma by x-ray studies. Exploratory laparotomy and resection of the involved area should be performed for potentially obstructing inflammatory lesions, thereby circumventing the risk of unsuccessful differentiation of the benign from the malignant process.

Female Pelvic Organs.—Seven cancers of the cervix have been found and proved. Five women were without symptoms and two had symptoms of pelvic disease when examined. Two women in the asymptomatic group had negative Papanicolaou smears, but suspicious areas noted during inspection of the cervix indicated the need for biopsy. In only one case (asymptomatic) was the cervix entirely normal in appearance and the positive Papanicolaou smear was the specific indication for biopsy which proved the presence of the carcinoma.

A total of 7,940 Papanicolaou studies have been performed. This includes both vaginal and cervical smears. Ninety-eight Class III (suspicious) reports were made, and ten Class IV (malignant cell) diagnoses were made. Seven of the above 108 patients had squamous cell cancer proved and treated. It is possible that an indeterminate number of the patients in whom a suspicious Papanicolaou has been reported, will eventually prove to have cervical carcinoma.

However, it must be emphasized, that visual inspection of the cervix with biopsy of any suspicious areas provides an excellent chance of detecting lesions early; particularly when such examinations are repeated at yearly or six-month intervals.

Endometrial Carcinoma.—Two endometrial carcinomas have been found, and both had symptoms and signs of disease (abnormal spotting). Papanicolaou smears were negative. Diagnosis was established by dilatation and currettage. Both patients are living and well after surgery. No good screening technique is yet available for *early* endometrial carcinoma. Bleeding and discharge from the cervical os, and uterine enlargement remain well-proved danger signs.

Ovarian Carcinoma.—Of forty-seven women who reported back to their physicians with a diagnosis of suspicious adnexal masses, five proved to have carcinoma of the ovary. Four of these patients were asymptomatic and one had symptoms. All were detected by means of bimanual palpation. In every case the surgical specimen revealed early cystadenocarcinoma of the ovary without spread to other tissues. All patients are living and well. Pelvic examination is the only method for detection of these early ovarian tumors. Laparotomy is necessary to establish the nature of a palpable mass.

Prostate.—Thirty-two patients were reported to have prostatic nodules suspicious for carcinoma. Twenty-one had resection or biopsy of the lesion, and seven carcinomas were proved histologically. We have accepted only histologic proof of malignancy, as against clinical impression. Nine patients have been treated for carcinoma of the prostate on clinical evidence only. It is curious that of all human malignancies, the diagnosis of prostatic cancer is commonly accepted on clinical evidence alone, whereas histologic or cytologic proof is demanded for other forms of cancer.

Three of the seven proved cases were asymptomatic, and four had symptoms of prostatic obstruction. Two of the symptom-free patients had bony metastases, as well as two of the patients with symptoms. One out of the four symptomatic patients is dead, and two of the three asymptomatic patients are dead. No satisfactory screening test is available for prostatic cancer. Unfortunately, widespread bony metastases are found in many patients at the time symptoms of prostatic obstruction appear. It is only conjectural to assume that repeated examination will significantly alter the outcome of prostatic cancer.

Skin.—Twenty-two patients have had skin cancer diagnosed at the Center. Fifteen of the lesions were basal cell carcinomas, and six were squamous cell carcinomas. One pigmented nevus proved to be a malignant melanoma. All of these lesions were small and localized; treatment has been successful, and all of the patients are well at this time. Fifteen of the twenty-two patients were aware of the presence of the lesion, but considered it benign and of no consequence.

Senile keratosis of the skin is considered a pre-malignant lesion and 183 patients have been found with keratoses. A total of 240 pigmented nevi, exposed to chronic irritation, have been reported, but only the one malignant melanoma has been demonstrated. No problem attends the diagnosis of skin cancer when clinicians are quick to submit biopsies of all suspicious lesions for histologic evaluation.

Lung.—Only one primary carcinoma of the lung was found in the first five years of function of the Detection Center. This lesion was far advanced and the patient had obvious symptoms of pulmonary malignancy. Two metastatic carcinomas were picked up, one a metastatic melanoma (not our melanoma patient) and the other a metastatic hypernephroma. No case of asymptomatic primary carcinoma of the lung has been detected, but one examinee was misdiagnosed, and will be reported in a following section. This is an unusual circumstance, perhaps owing to the exceptionally good detection of lung lesions in the mobile unit chest survey which has been extensively used in our State. Willingness on the part of our examinees to participate in a cancer detection program indicates a likelihood that they availed themselves of the opportunity for a chest x-ray examination.

There are no pathognomonic symptoms of *early* lung cancer. When symptoms are present during the earliest *phases* of lung cancer, they are the same as those produced by common respiratory diseases. These symptoms often respond to non-specific treatment, and serious delays in accurate diagnosis and treatment are fostered. The highly lethal nature of lung cancer makes it imperative that clinicians exercise a high index of suspicion towards silent lung nodules (coin lesions) and other suspicious pulmonary changes if a significant increase in five-year survivals is to be effected.

Breast.—Ninety-two women had breast lesions considered suspicious for the presence of cancer. Seven (9 per cent) carcinomas have been proved at surgery, and seventy-seven lesions have been established as benign. Eight lesions are not yet fully diagnosed. All of these tumors were unknown to the patients at the time of examination.

Six patients are living and well, and one is dead of cerebral metastases fifteen months after surgery. At the present time periodic physical examination of the breasts is the only proved method of detecting this cancer.

Urinary Tract.—The kidney has been a difficult organ to survey with detection techniques. Routine urinalysis for detection of urinary tract bleeding has not been adequate as an indication of the need for advanced roentgen studies. Most kidney lesions are large enough to be palpated during physical examination before they have invaded the renal pelvis and caused urinary tract bleeding. The Detection Center missed the diagnosis in two patients who subsequently developed adenocarcinoma of the kidney. In the absence of an adequate screening technique, and with widespread use of roentgen pyelogram unfeasible, we probably will not improve in diagnosing these patients in an asymptomatic stage of the disease. No testicular or penile cancers have been found.

Lymphatic System.—Of six patients found to have lymphatic leukemia, four had palpable lymph nodes at the time of examination. Only one was asymptomatic. Five had symptoms of a mass, pain or weakness. There were forty-six patients with a lymphocyte count above 45 per cent, and thirty-nine patients of this group have not developed a lymphoma to the present time. Four of the six leukemia patients are alive up to five years after treatment.

Thyroid.—One papillary adenocarcinoma of the thyroid was proved at surgery, and one lymphosarcoma of the thyroid was found. These glands were diagnosed as the sites of suspicious nodules. A total of eighty-six thyroid adenomas have been reported. Thirty-five of these have been surgically excised. We believe about seven per cent of palpable, single, thyroid nodules will prove to be malignant (University of Minnesota study).

TABLE VI. PRE-CANCEROUS LESIONS

Total Number	1300
Adenomas and polyps of rectum and colon	624
Gastric polyps	6
Kraurosis vulvae	16
Leukoplakia	144
Pigmented nevi (areas of irritation)	240
Polyps of vocal cords	1
Senile keratosis	183
Thyroid adenomas	86

Pre-Cancerous Lesions.—Table VI presents eight lesions considered to be pre-cancerous and the number of patients detected with these conditions. It is impossible to calculate the potential salvage in this large segment of the over-all group (24 per cent) through *prevention* of malignancy by application of appropriate therapy during the pre-malignant stage of such lesions.

Known Failures of the Detection Center Program During Five Years Operation.—It is to be expected that a few cancers might arise in such a manner that detection center procedure would not screen out the lesion, or that failure of an examinee to co-operate would result in late diagnosis. Furthermore, an occasional misinterpretation of roentgenograms might result in undue delay in establishing the histologic nature of a questionable lesion. Table VII presents nine examinees who developed cancer during the interim period between examinations, and were not picked up at the last negative examination.

Two patients with carcinoma of the kidney were asymptomatic at examination two months and ten months prior to diagnosis. Urinalyses were negative, and abdominal palpation was negative; criteria indicating the need for intravenous pyelograms were lacking. Since intravenous urography is not feasible as a routine procedure, and since most renal neoplasms in adults attain considerable size before invasion of the renal pelvis causes symptoms or signs of disease, a better method of screening for renal neoplasms is urgently needed. These patients demonstrate an inadequacy of the present examination procedure for renal lesions.

The gastric cancer appeared in a patient who previously had a subtotal gastrectomy for duo-

TABLE VII. KNOWN DETECTION CENTER FAILURES DURING FIVE YEARS OPERATION

	Time from CDC Exam. to Positive Diagnosis	Conditions
Kidney	2 months (surgery)	Urine negative. Prostate questionable. Recheck by LMD disclosed renal lesion. Failure of examining method.
Kidney	10 months (surgery)	Examination and urinalysis at CDC negative. Failure of examining method.
Stomach (carcinoma)	25 months (surgery)	Subtotal resection 1923 for duodenal ulcer. X-rays and exam. at CDC negative. Patient refused follow-up exams by CDC & P.P.
Sigmoid (carcinoma)	4½ months (surgery)	Exam. at CDC diverticulitis. Exam. by LMD same. Then developed bleeding and procto biopsy positive. Failure of examining method.
Left Lung (carcinoma)	18 months (surgery)	Jan. 1949—apical lesion seen here. Diagnosed fibrosis. Jan. 1950—diagnosed same. Summer 1950—carcinoma.
Tonsil (undifferentiated carcinoma)	8 months (biopsy)	Negative exam. at CDC 8 months prior to symptoms.
Neck (lymphosarcoma)	8 months (died)	No indications 6 months prior to death.
Prostate (carcinoma)	14 months (died)	Previous trans-urethral resection for prostatism, 1946. Died of heart disease; cancer prostate incidental finding.
Unknown (abdominal carcinoma)	14 months (died)	1949—Papanicolaou Class III—biopsy of cervix negative. Exam. 1950 negative. Failure recheck appointment.

denal ulcer. Gastrointestinal series x-rays were negative for tumor at the time of the CDC examination. The examinee failed over a twenty-five-month period to return to either the Cancer Detection Center or his own physician for check-up. It is reasonable to assume that the gastric malignancy developed during that period of time, for the silent interval of most gastric cancers is in the nature of twenty to twenty-two months. Patient failure appears to be the responsible factor in this instance.

The carcinoma of the sigmoid represents a failure to correctly interpret the colon roentgenograms. A diagnosis of inflammatory stricture secondary to diverticulitis was made at the Cancer Detection Center, and confirmed with further x-ray studies by the family physician. An episode of bleeding shortly after the second x-ray examination led to biopsy of the area through a sigmoidoscope and the maligant character of the constriction was established. The roentgenologist must exercise caution in attempting to differentiate between lesions of the colon causing stricture. Laparotomy with excision of the diseased part is the safest course to follow in any case of large bowel stricture.

The lesion of the left lung was noted on two chest films taken at the Cancer Detection Center one year apart. Six months following the second diagnosis of pulmonary fibrosis the patient developed symptoms, and chest x-ray showed progression of the lesion. Thoracotomy then established the malignant character of the tumor. Failure to strongly advise thoracotomy rests with the Detection Center. Pulmonary lesions must be established histologically at thoracotomy if sputum studies and bronchoscopic biopsy fail to establish the diagnosis. Undue delay is particularly tragic with this lethal carcinoma.

One carcinoma of the tonsil and one lymphosarcoma of the neck appeared eight months after a negative examination at the Detection Center. There was no evidence of tumor in either patient at the time of examination at the Detection Center. Another patient was found to have carcinoma of the prostate as an incidental autopsy finding following death due to cardiac disease. The last patient died of carcinomatosis fourteen months after a negative examination. The source of the primary tumor was obscure at autopsy.

A recent survey of examinees who failed to return for recheck examinations has not brought other cases of "missed cancers" to our attention. This latter group represents 9 per cent of the hundred cancers known to be present in the entire five-year period.

Of the ninety-one cancers correctly diagnosed in the Cancer Detection Center, thirty-two were established by roentgenograms of one kind or another. Only two of the "missed" cases were examined with x-ray methods and these constitute 6 per cent failure for roentgen ray diagnosis during the five years of operation of the center. This compares favorably with diagnostic experience in the x-ray department of the University of Minnesota Hospitals. All roentgen diagnostic methods have specific limitations, and clinicians responsible for patients must appreciate the necessity of bringing other more specific methods (microscopic examination of tissue) to bear on questionable cases.

Sixty-nine of the cancers correctly diagnosed were found either during physical examination or with a laboratory test. If we consider six of the "missed" lesions as failures of physical diagnosis, this represents 8 per cent inaccuracy as far as missing malignancies is concerned. It must be remembered, however, that many lesions were reported as suspicious (prostate, ovary, breast, thyroid) and proved to be benign. Again, the shortcomings of gross palpation or inspection are obvious, and the necessity for histologic and cytologic verification is amplified.

Summary

1. During five years' operation of the Cancer Detection Center at the University of Minnesota ninety-one malignancies were found in 5,352 examinees. A total of 11,343 examinations were performed. This represents seventeen cancers per 1,000 patients examined (1.7 per cent), or 7.9 cancers per 1,000 examinations performed.

2. Forty-six examinees with cancer were symptom free for the organ or organ system in which the lesion was found. Forty-five had symptoms indicating a likelihood of cancer in the organ or organ system involved. In the asymptomatic group twenty-four cancers were found at recheck examination, indicating the value of repeated examinations to detect malignancies in their earliest stages.

3. Only in cancer detection centers, or cancer prevention clinics are large numbers of persons surveyed for cancer while they are without symptoms of disease. It seemed of value to emphasize the difference in survival between symptomatic and asymptomatic examinees found to have cancer in this study.

4. Three of six asymptomatic gastric cancer patients are alive and well up to four years after surgery. There is one survival among five gastric cancer patients who were symptomatic at the time of diagnosis. Of thirteen patients with colon cancer who were free of symptoms at time of diagnosis, eleven are living and well (seven over three years). Only one of the five colon cancer patients with symptoms at time of diagnosis is living (two years). These results appear to substantiate the increased value of early diagnosis in terms of survival.

5. Twenty-four per cent of our patients had pre-cancerous lesions. The value of treatment of these lesions in the prevention of cancer is incalculable.

6. Of all cancers developing in our examinees during this five years, 9 per cent are considered failures of the Detection Center method. Roentgen ray techniques failed in 6 per cent of the thirty-four patients in whom the diagnosis was established by this modality. Misinterpretation of x-ray changes was the responsible factor. Of the cases detected by means of physical examination and laboratory studies 8 per cent must be considered as failures for this method.

7. We believe that several types of serious malignancy can be identified in advance of their usual signs and symptoms through the application of a well conceived, routine, cancer detection examination performed at yearly intervals.

FARMER'S LUNG

A Form of Bronchopulmonary Moniliasis

PHILIP H. SOUCHERAY, M.D.
Saint Paul, Minnesota

IN RECENT MONTHS some instances of chronic pulmonary disease in farmers have been observed which share certain features in common. Each gave a history of uncomfortable exposure to the dust from moldy silage, each was ill for a period of months complaining of dyspnea or cough, and each improved on removal from his environment.

Case Reports

Case 1.—The first man was a dairy farmer forty-four years old, who presented himself in April, 1953, with the complaint of abdominal soreness and constipation associated with loss of ambition and a 20-pound weight loss of four months' duration. Physical examination disclosed a few palpable posterior cervical lymph nodes, and some tenderness in the epigastrium and right lower quadrant of the abdomen. The blood hemoglobin was 12.9 Gm., and the white cell count was 8,400 per cu. mm. with 77 per cent neutrophils, 12 per cent lymphocytes, 5 per cent monocytes, and 6 per cent eosinophils. The Wasserman test gave negative findings. The histoplasmin and tuberculin skin test findings were also negative. X-ray examination of the gastrointestinal tract showed only tenderness and spacticity over the duodenal bulb and colon. The chest x-ray examination revealed blunting of the costo-phrenic angles, a small amount of fluid in the right major interlobar fissure, and a mottled infiltration of both mid-lung fields extending out to the periphery. Upon questioning, the patient stated that he had been experimenting with a method of storing silage dry in the open field. He was quite disgusted with the method because every time he went out to the field storage area to get a load of silage for his cattle, he was distressed with suffocating chest pain after inhaling the dust from this moldy silage.

He also stated that two other farmers in an adjoining county had been storing silage in the same manner, and had noted respiratory distress following inhalation of the dust. They had been told at the University of Wisconsin Hospitals that they were probably allergic to something in their silage. When seen four months later, eight months after the onset of his illness, he felt improved, but he had done no farm work in the interval. The chest radiograph showed resolution of the previously noted infiltration into streaks of small nodular densities radiating out from the hilum.

Case 2.—The second case was that of a dairy farmer forty-six years old, who began to note a productive cough and shortness of breath in the fall of 1953. By the end of the year, he was unable to do any work and at times required adrenalin by injection to relieve his nocturnal dyspnea. Treatment with several different antibiotics given one after the other for two to four weeks at a time apparently gave him little relief from his symptoms. No notes concerning the physical examination during the acute phase of the illness were available from the referring physician, but when the patient was first seen in May, 1953, he was rather pinched and anxious in appearance and had a slate gray cyanosis of his skin and mucous membranes. There were no expiratory wheezes audible, but on inspiration there were many sticky and crackling râles. Blood hemoglobin was 18.5 Gms. per cent and the white cell count was 8,550 per cu. mm. with 75 per cent neutrophils, 13 per cent lymphocytes, 9 per cent monocytes, 2 per cent basophils, and 1 per cent eosinophils. The sputum was viscid and contained non-hemolytic streptococci, coagulase negative staphylococci, and some eosinophils. No fungi were demonstrated by smear or culture. Tuberculin and histoplasm skin test findings were negative. X-ray examination of the chest at monthly intervals, commencing in January, 1953, had shown a finely mottled type of density distributed widely through both lung fields. By May, 1953, there was some clearing of the widespread infiltrations without coalescence of nodules or formation of fibrous residuals. This man stated that he had not finished his new silo in the fall of 1952, and had to rely on silage left standing in the cattle barn or trucked into the barn from neighboring farms. Inhalation of the dust from this silage caused so much dyspnea and cough that he was unable to carry on through the winter with the daily chore of pitching of silage out to the cattle. This work was finally delegated to his wife who seemed to handle the job without much trouble.

Case 3.—The third case is that of a farmer, sixty-four years old, who stated that he had noted considerable respiratory distress after handling moldy hay over several winters. He felt that he was suffering from repeated upper respiratory infections. In March, 1953, he noted the onset of a cough productive of two or three ounces of thick yellow sputum daily. Dyspnea on slight exertion was severe, and there were frequent wheezing respirations. On physical examination crackling râles were noted over both lungs, and there was cyanosis of the lips and nail beds. The remainder of the examination was without note of abnormality. Blood hemoglobin was 14.7 Gm. per cent and the white cell count was 6,450 per cu. mm. with 72 per cent neutrophils and 2 per cent eosinophils. Sputum smears and cultures failed to demonstrate pathogenic bacteria or tubercle bacilli, but Candida albicans was isolated from sputum culture on three occasions and a penicillium on one other occasion. X-ray examination of the chest showed finely mottled densities scattered through both lung fields. Over a period of

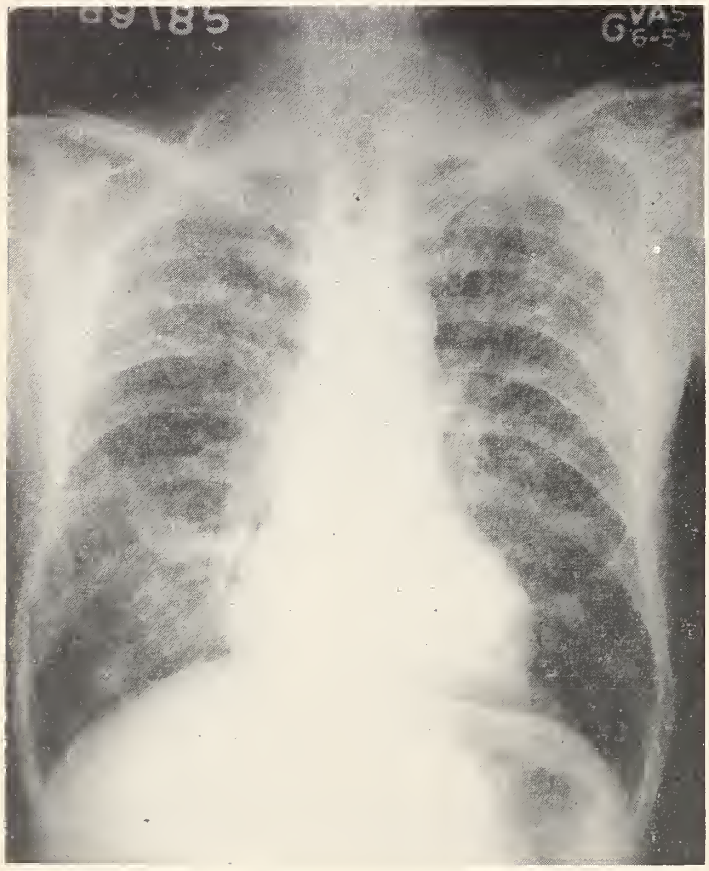
two months in the hospital, there was noticeable clearing of the diffuse infiltration, and the dyspnea was less severe than on admission.



Roentgenogram of chest in third case* after clearing of the acute pneumonia. There are widespread fibronodular infiltrations radiating from each hilum.

Discussion

These three cases of idiopathic pneumonitis, or pneumoconiosis of farmers, had some features obviously in common, and seemed to resemble those cases of "farmer's lung" recently summarized from the British and Scandinavian literature by Fuller.[3] In England, roentgenologists have been describing an occupational pneumonitis among farmers for over twenty years.[2] They have recognized in farmers exposed to the dust of "burnt" hay or moldy grain at threshing time a bronchitis which may go on, after repeated exposure, to a kind of bronchopneumonia, and, after many years of repeated exposure, to a fibro-cavitary disease roentgenologically indistinguishable from tuberculosis. A high spore count for molds of the Fungi imperfecti was obtained from the airborne dust in either the cattle barns or from the threshing floors where these people worked. In most instances, the Monilia, Candida albicans, was recovered from the sputum of the infected workers.

Whether or not these cases represent instances of primary pulmonary moniliasis is certainly open to question. There is little doubt but that primary pulmonary moniliasis can occur, but it is extremely difficult to make the clinical diagnosis of that disease.

Castellani,[1] in 1905, described "tea-tasters cough" and pneumonitis in persons employed in the dusty tea warehouses of Ceylon. Tea-tasters crushed the dried tea leaves in their hands before sniffing them for aroma while coolie laborers carried bags of dried leaves around within the dusty warehouses. Both groups developed a peculiar cough, and it was known that laborers who became ill while working in the warehouses would recover if employed in some outside work for a time. Candida albicans was found in the dried tea leaves, was recovered from the sputum of sick men, and was made to reproduce the disease in animals. This last was accomplished by forcing a guinea pig to inhale daily over an eleven-month period the tea leaf dust contaminated with Candida albicans.

A brilliant demonstration of the pathogenicity of certain strains of Monilia was made by Dr. Kano Ikeda[4] of Saint Paul and was reported in 1936. He collected five cases of bronchopulmonary moniliasis occurring both as part of systemic moniliasis in debilitated persons as well as primary pneumonia in young individuals exposed to a dusty atmosphere. One particularly virulent strain was isolated from a young man with pneumonia and empyema due to Candida albicans. When this organism was inoculated into rabbits by the intravenous route, they died within a few days of uremia. When the inoculation was intratracheal, a bronchopneumonia developed. When the inoculation was made into the lung by a direct stab through the chest wall, the injured lung offered little resistance to infection and a severely destructive pneumonia resulted. Ikeda also noted the presence of both sub-miliary tubercles and obstructive thickening of the walls of smaller arterioles in the inoculated rabbit lung as well as the human autopsy material he examined. This is particularly interesting in the light of recent work performed by Lennart Zettergren in Sweden.[5]

In 1950, Zettergren reported on an experiment to determine the rôle played by organic dust in the causation of bronchopenumonia in persons working on threshing rigs. He found the dust from a threshing machine to be heavily infested with Candida albicans. The monilia organism was propagated on wort agar while the dust was sifted and sterilized. A chamber was then constructed in which a rabbit could be confined in an atmosphere heavily contaminated with sterile threshing dust. The first group of rabbits was exposed for an hour a day for fourteen days to the dust alone, and the lungs were then examined as the animals were sacrificed at intervals of a few weeks following exposure. A second group of rabbits was exposed to the sterile dust innoculated with the monilia culture, and the lungs were then examined in the same manner as with the first group. In both groups of animals, there was evidence early of irritative bronchitis due to the dust. Both groups showed submiliary granulomata in the neighbhood of the terminal or respiratory bronchioles. These granulomata persisted only a few weeks in the animals exposed to dust alone, but showed caseation and persisted much longer in the animals exposed to dust and the fungus. In addition, the second group of exposed animals showed thickening of blood vessel walls in the terminal arterioles, some being almost obstructed. No fungi were demonstrated in the granulomata, but numerous fat-filled macrophages were seen in the caseating granulomata.

The most interesting thing about Zettergren's descriptions of the pathologic changes in the rabbit lungs was that it was almost identical with Dr. Ikeda's descriptions of the changes in both human and rabbit lungs reported fifteen years ago, although there is no indication that Zettergren was familiar with Ikeda's report. It is apparent that the granulomata accounted for the miliary picture seen on the chest radiograph and it seems reasonable to assume that the arteriolar obstruction accounted for the pulmonary congestion and the cyanosis noted in the subacute phase of the reported cases. The hemoglobin value of 18.5 Gm. per cent in one of the reported cases and a similar elevation in an unreported case seen at the University Hospital since these cases were collected is conceivably a compensatory polycythemia in response to the chronic hypoxia caused by the arteriolar obstruction.

These cases are not presented as authenticated instances of pulmonary moniliasis. As previously stated, diagnosis is extremely difficult to make in the acute phase of the illness and is nearly impossible to make in the chronic state except by lung biopsy and tissue culture. However, these cases do fulfill the requirements for making a presumptive diagnosis of pulmonary moniliasis, each patient having been exposed to an irritating dust from a moldy source and each demonstrating the roentgenological and clinical picture that has been associated with proven cases of pulmonary moniliasis.

Ordinarily, in our temperate climate, we should not expect to find much monilial infection, but with the unusually wet field conditions of recent years, we should anticipate much greater exposure to fungi among our agricultural workers. Mycotic pneumonitis must be considered in any case of persistent pulmonary disease in farmers. Since the fungi grow so freely after antibiotic therapy in such a large percentage of people so treated, it becomes increasingly important to identify pathogens before instituting therapy for pneumonitis. In unusual cases, the bronchoscopic aspiration of secretions is essential to by-pass the usual contaminants in the upper respiratory tract when material is needed for diagnostic culture. It is to be hoped that when atypical pneumonitis in farmers is encountered in the future that interested persons may seize the opportunity to identify the causative organisms and trace them to their source. This procedure will reward the investigator because if fungi are found to be causing the pneumonitis, they will frequently prove susceptible to iodides whereas antibiotics will have little effect and may even enhance the growth of fungi.

Farmers certainly should be dissuaded from employing farm practices that result in the propagation and dissemination of moldy dust, for the pulmonary mycoses are extremely debilitating and may leave permanent residuals, if exposure is repeated.

UPPER GASTROINTESTINAL HEMORRHAGE

OWEN G. McDONALD, M.D., R. H. LaBREE, M.D., and M. G. GILLESPIE, M.D.
Duluth, Minnesota

A FORTY-FIVE-YEAR-OLD man was first seen in June, 1950, with a history of incomplete recovery from "flu." His complaints were of minor, indefinite aches and pains in the chest and epigastrium. His general appearance and health were good. He did have a past history, however, of excessive use of alcohol. The general physical examination and routine blood studies, as well as x-ray examinations of the chest, colon, esophagus, stomach, and duodenum, all gave negative findings.

Five weeks later, he became weak and faint and was admitted to his local hospital. The next day he vomited blood and had two large bloody bowel movements. During the following three weeks, he had repeated massive upper gastrointestinal hemorrhages requiring thirty-five transfusions. He was seen by many consultants from whom came a variety of opinions. His condition prevented operative treatment and he expired. A small ulcer high on the lesser curvature was disclosed at a postmortem examination. In its base there was a small ruptured aneurysm of a branch of the left gastric artery. A thrombotic mass with signs of organization was attached to the intima of the most superficial part of the blood vessel.

This case and repeated experiences with sudden severe gastrointestinal hemorrhage stimulated a study of such cases admitted to St. Mary's and St. Luke's Hospitals of Duluth during the ten-year period ending December 31, 1952.

The case histories of 424 patients were reviewed (Table I). There were 341 males and 83 females; a ratio of four to one. Approximately 30 per cent of the patients were under forty-five years of age.

The severity of the hemorrhage was arbitrarily graded mild, moderate, and massive (Table II). In mild hemorrhage, the hemoglobin range was from 100 per cent down to 75 per cent, and the red blood cell from five million down to three and one-half million. In moderate hemorrhage, the hemoglobin ranged from 75 per cent down to 50 per cent and the red blood cell count from three and one-half million to two and one-half million. In massive hemorrhage, the hemoglobin ranged from 50 per cent downward and the red blood cell count from two and one-half million on down. Seventy-one cases were graded as mild, 179 as moderate, and 174 as massive hemorrhage (Table III). Patients over forty-five years of age showed essentially the same distribution in the grades as those under forty-five years of age (Table IV). Ninety-four (22 per cent) of the cases had no record of an x-ray examination and in twenty-three (5 per cent) no abnormality could be demonstrated by x-ray examination or exploratory operation (Table V). In those with an established diagnosis, the bleeding was due to duodenal ulcer in 70 per cent, gastric ulcer in 10 per cent, and a variety of pathologic conditions in the remaining 20 per cent.

	Hbg.	RBC
Grade 1 Mild	100—75%	5 M—3.5 M
Grade 2 Moderate	75—50%	3.5 M—2.5 M
Grade 3 Severe (massive)	50— 0%	2.5 M—0 M

A review of these cases also yielded these miscellaneous observations: (1) alcohol and irregular eating habits seemed frequently to predispose to bleeding; (2) esophageal hemorrhage was usually massive and recurrent hemorrhages were common; (3) thirty-seven patients had had forty-two operations mostly for duodenal ulcer or its complications; (4) the x-ray diagnosis of gastritis and gastroduodenitis was fairly common. However, it is possible that in some of these patients the hemorrhage was due to tiny mucosal erosions not detected by x-rays; (5) less common lesions of the stomach, duodenum and jejunum should always be kept in mind. This is especially true of lesions of the jejunum and the second and third portions of the duodenum; (6) fatal hemorrhage occasionally followed reduction of fractures and other unrelated abdominal operations.

Since the treatment of these patients was carried out by many physicians, variations were common. Eighty-one patients were operated upon; seven as emergencies, sixty-six while still in the hospital but after bleeding was controlled, and eight returned to the hospital at a later date for

surgery (Table VI). In this group sixty-five had had moderate or massive bleeding. The majority (80 per cent) were found to have benign ulcerations of the duodenum or stomach. In 15 per cent, the lesion belonged to a miscellaneous group, mostly benign or malignant tumors. In 5 per cent, no source of bleeding was found (Table VII).

There were six postoperative deaths, a mortality of 9 per cent. Five followed resection of the stomach for bleeding duodenal ulcer. Of these, two were due to late hemorrhage, the result of erosion of the pancreatico-duodenal artery; two were the result of a blown-out duodenal stump and one patient had a non-functioning stoma and complete wound dehiscence. One death followed negative exploratory operation in an individual who died four days postoperatively from another hemorrhage (Table VIII). Postmortem examination revealed a small ulcer high on the posterior wall near the lesser curvature in the base of which was an open blood vessel, a branch of the left gastric artery.

By comparison, 282 patients with grade II and III hemorrhage were treated medically. In this group, there were thirty-eight deaths, a mortality of 13.5 per cent (Table IX).

There were six (6.2) deaths among ninety-six patients below the age of forty-five with grades II and III hemorrhage, while in the group over forty-five years with grades II and III hemorrhage, there were thirty-eight deaths, a mortality of 15 per cent (Table X). Fatal exsanguination occurred in one half of the cases in the older group. Also, as one might expect in the older age group, co-existing lesions were common. Diabetes, cirrhosis, hypertension, hypertensive cardiovascular disease, coronary sclerosis, and arteriosclerosis were frequently associated.

Discussion

A more aggressive surgical attitude is in order because, in the first place, the past decade has shown a remarkable advance in major surgery as evidenced by a mortality rate of less than 2 per cent for partial gastrectomy for peptic ulceration of the stomach or duodenum. Antibiotics, blood banks, and better anesthesia and techniques are among the factors contributing to this improvement. Secondly, medical management has yielded no comparable improvement.

When bleeding continues or recurs despite adequate medical care, surgical intervention is imperative. At operation, the abdomen should be thoroughly explored. The source of bleeding, if found, should be controlled. If it is a duodenal ulcer, the pancreatico-duodenal artery should be ligated, the ulcer excised if possible, and two-thirds or three-fourths of the stomach resected. If the source of bleeding is a gastric ulcer, two-thirds or three-fourths of the stomach should be resected, including the pylorus, the antrum, and the greater part of the lesser curvature. The left gastric vessels should always be ligated and divided. In those patients in which exploration, including duodenotomy and gastrotomy, does not reveal the source of bleeding, it is mandatory to perform a partial gastrectomy and this must again be a two-thirds or three-fourths resection with ligation and division of the left gastric artery.

Summary

A study of 424 cases of upper gastrointestinal bleeding is presented.

In 80 per cent of the cases, peptic ulceration was the cause of bleeding. In 15 per cent, there were other lesions of the stomach, duodenum, and jejunum. In 5 per cent, routine examinations or exploratory operations failed to disclose the source of bleeding. Sixty-five patients with moderate or severe hemorrhage were operated upon with a mortality of 9 per cent. The cause of death in each case was due to a failure in surgical technique or judgment.

The mortality under medical management was 13.5 per cent.

The death rate for upper gastrointestinal hemorrhage in those below forty-five years of age was 6 per cent as compared to 15 per cent in individuals over forty-five years. Exsanguination was the mode of exit in half of those cases in the older age group.

Conclusion

A more aggressive surgical attitude towards severe upper gastrointestinal hemorrhage is justified.

PSITTACOSIS REPORTED

According to the U. S. Public Health Service, psittacosis virus was recently recovered from two parrots sent to a game farm in Virginia. X-ray examination of the attendant who cared for the birds showed evidence of pneumonitis about one week after discharge from a hospital where he was treated for pneumonia. A specimen of blood from the attendant was positive 1:8 with Lygranum antigen.—Psittacosis infection was reported in three parakeets in Connectciut, one of which had been imported from Florida and two from New York City from a source which had previously been incriminated. Reports have been made of four suspected cases in human beings and of two actual cases of psittacosis, in both of which the blood showed a positive complement fixation test in a titer of 1:128.

Pursuant to information received from the Tennessee health commissioner, indicating that human cases of psittacosis in that state had been traced to contact with parakeets purchased in North Carolina, an investigation by the North Carolina State Board of Health disclosed six cases of atypical pneumonia in the family of the owner of the aviary from which the parakeets had been purchased. It was reported that a large number of persons raise psittacine birds in this area and that many cases of atypical pneumonia have occurred. Blood samples and several birds have been sent to the virus laboratory of the Communicable Disease Center.—J.A.M.A., Vol. 154, No. 12, March 20, 1954.

OBSTRUCTION OF THE SMALL INTESTINE

Survey of Cases in a Small Group Practice

JOHN C. MICKELSON, M.D.
Mankato, Minnesota

OBSTRUCTION of the small intestine is an important surgical condition, since almost certain death results if it is left untreated. Special impetus to research problems in obstruction has emanated from the University of Minnesota. Emphasis by Wangensteen on correction of electrolytic and fluid balance and early decompression with or without laparotomy has resulted in a decreased mortality.. His complete and concise summary of this subject is readily available.[1]

All of the cases of small bowel obstruction in the past twenty-five years treated only by operative means at the Mankato Clinic are presented. Major surgical procedures at both the Immanuel and St. Joseph's Hospitals totaled 15,740, and of these 257 patients were operated upon for small bowel obstruction. There were fifty-six hospital deaths in this group (Table I).

The clinical picture of intermittent crampy abdominal pain, nausea, vomiting, and distention is well known. Most patients with suspected obstruction were treated with indwelling nasal catheter drainage, abdominal hot moist packs, intravenous fluids, and analgesics. The degree of distention was evaluated periodically with abdominal x-rays and simply measuring the circumference of the abdomen with a tape. Failure to respond to this regime in twenty-four hours, as evidenced by increasing toxicity and distention, prompted operation. Patients with an obviously strangulated hernia or suspected strangulated gut were immediately operated upon. If the surgeon's description indicated compromising of the blood supply, the obstruction was noted as being of strangulated type; all others were considered simple. The exact site of the obstruction was difficult to determine. Again, the description by the surgeon of the operative findings was used as a means of classification. Duodenal obstruction was not included since this organ for the most part was obstructed at or near the pylorus by gastric or related lesions. In general, if the location of the obstruction was jejunal, it was classed as high, and if in the lower one-third of the ileum it was considered low. Admittedly, this was not too reliable when dealing with distended bowel of questionable viability, but it served to indicate that most of the lesions were in the lower small bowel (Table I). Multiple surgical procedures were utilized and sometimes several in the same situation. It was our operative policy to facilitate decompression by the easiest means, to remove devitalized tissue and re-establish continuity if possible. Before the more common use of intestinal intubation by an indwelling nasal catheter, ileostomy was an accepted method of combating paralytic ileus. The patients in our study commonly had ruptured appendices or other septic conditions and were in extremely poor condition. The additional trauma of this procedure and the absence of antibiotics particularly, contributed heavily to the over-all mortality. The lack of knowledge regarding principles of treatment now well established and the fact that transfusions were not ordinarily used were also contributory to this high figure in early days. The patients expiring in our hospitals had various causes of death, most of which were quite obvious, though few were proven by autopsy. This is unfortunately common in many private institutions.

TABLE I. SMALL BOWEL OBSTRUCTION SURVEY
Mankato Clinic (1927-1952)

	No. Cases	Percent
Total major surgical procedures (through 1952)	15,740	
Small bowel obstruction treated by operative means	257	1.3%
Hospital deaths	56	22% (1947-1952) 6.5%
Site of Obstruction		
Low	250	97%
High	5	2%
Unknown	2	1%
Type of Obstruction		
Strangulated	130	50+%
Simple	127	49+%

The series was equally divided as to sex, the male patients being but slightly more commonly afflicted than female. In this section, there are virtually no colored people so all of the patients were white. As one might surmise, most of the patients were over fifty years of age. Youth and early middle age contributed 24 per cent of the operations, while there were few in the very young (Table II).

TABLE II. SMALL BOWEL OBSTRUCTION SURVEY

	No. Cases	Percent
Sex and Color		
Male	135	53%
Female	122	47%
Black	0	—

Remove stone	3	1%
Short circuit	3	1%
Remove pin	1	Less than 1%
Mortality		
Peritonitis	31	55%
Shock	6	10%
Toxemia	5	9%
Carcinomatosis	4	7%
Cardiovascular	4	7%
Not known	3	5%
Pulmonary embolism	2	3%
Gas gangrene	1	1%

Unfortunately, 45 per cent of the patients had symptoms which lasted more than forty-eight hours. This was a definite contributory factor to mortality as will be shown later. A fair number were operated upon in less than twelve hours. These were mostly strangulated external hernia in which the diagnosis was readily apparent and of necessity came to early operation. Although the site of the obstruction was difficult to determine, there was a strikingly high incidence of obstruction in the lower small bowel. The number of strangulated and simple types were equal (Table II).

The obstructions were caused predominantly by herniations. Forty-six per cent of our cases were due to hernia of one type or another. None was included which did not have an obstructed loop of small bowel. Several such loops reduced themselves after spinal anesthetic was administered. We prefer this type of anesthetic. The surgeon's notes, however, indicated that the bowel showed definite evidence of obstruction and usually strangulation. Both of our cases of internal hernia were due to defects in the omentum of the lower ileum. Postoperative adhesions were found in seventy-two cases. Talc used in preparing rubber gloves has proven to be a peritoneal irritant and causes adhesions. For several years now, as elsewhere, nonirritating starch powders have been substituted by our operating staff. Ruptured appendices obstructed either mechanically due to abscess formation or by adhesions in twenty-four cases. This was found chiefly in the early days of clinic practice. All of the intussusception cases were of the ileocecal type. Ileus, as we know it today, was treated at that time by surgical intravention and in nine cases an appropriate ileostomy was performed. Carcinoma of the bowel in every case orginated in the colon and caused blockage by peritoneal spread or metastases to the small gut. Other sources, volvulus, gallstones, bands, et cetera, were found very infrequently (Table III).

The operative procedures in the various cases were dependent upon the type and cause of obstruction. Simple lysis of adhesions was accomplished in one-fourth of the cases. Ileostomy was deemed necessary in one-fourth of this group also, either as a proximal decompression safety valve in resections which were necessary in a fair number of instances, or as a direct attack upon the obstruction *per se*. Because of the high incidence of hernia, release of the bowel and repair of the hernia by one method or another was done most often. As one can readily see, circumstances usually permitted this combination, but in a few instances doubtful tissue viability prevented hernia repair (Table IV).

Investigation showed that peritonitis was by all odds the biggest cause of death. It was difficult to separate shock and toxemia in obstructed patients, but in earlier days shock following oper-

TABLE V. SUMMARY OF MORTALITY

ation was common, and that is what this figure represents. Carcinomatosis due to primary carcinoma of the colon in our series was found to be the cause of four deaths. Cardiovascular disturbances, coronary occlusion, and pulmonary embolism were found in a surprisingly small number of cases, considering the high incidence of our patients in the upper age groups (Table IV).

In summarizing our mortality, male and female patients were involved practically identically. Sixty-six per cent of the dead patients were over fifty years of age. Curiously enough, simple obstruction was found in 62 per cent of the fatal cases, while strangulated conditions existed in only 38 per cent. As previously mentioned, the duration of symptoms was a definite factor in mortality, 64 per cent of our patients having symptoms more than two days (Table V). Adhesions were found in 25 per cent and hernias in 20 per cent. The remainder of the etiological agents were of lesser significance. Ileostomy was done in 58 per cent of the patients who died, which would indicate that if such a procedure were deemed necessary, the patient was in very critical condition or tissue viability prevented reestablishment of continuity. It did not mean presumably that the operation itself was a contributing factor in the death, although, in earlier days, the additional insult of such a procedure was a definite factor in the high mortality which we have encountered (Table VI).

It is interesting to note that a male or female patient with small bowel obstruction had a one in five chances of death. In those fifty years of age or above and, curiously enough those with a simple hernia rather than a strangulated hernia, chances of survival were considerably decreased. All of our patients with mesenteric thrombosis expired. Internal hernias, likewise, carried a high mortality. Half of the patients requiring ileostomy expired.

During the past five years, with strict attention to the excellent principles mentioned and earlier operation in questionably secure patients being treated conservatively, our mortality has dropped to 6.5 per cent (Table I).

THE FAMILY DOCTOR

The family doctor has in general a commendable composite of wide interests or receptivity to ever-broadening developments in the various aspects of total medical practice, of an inevitable understanding of his patients that goes beyond Johnnie's pimples and Mary's menstrual cramps and Susie's loss of weight due to lack of appetite—beyond the peptic and other complaints and into life stresses and global biologic considerations. These aspects of medical practice on the part of the family doctor are inevitable because he finds himself as a matter of course in the peculiar position of friend, adviser, and dependency symbol; this is the complete physician, this is the family doctor.—Jess V. Cohn, M.D., in *Pennsylvania Medical Journal.*

THROMBOTIC THROMBOCYTOPENIC PURPURA

Report of a Case

HAROLD E. MILLER, M.D., and FREDERICK H. K. SCHAAF, M.D.
Minneapolis, Minnesota

THROMBOTIC thrombocytopenic purpura is characterized pathologically by generalized hyaline arteriolar and capillary thrombi and clinically by a fulminating thrombocytopenic purpura accompanied by hemolytic anemia and transient renal, cardiac, and neurological manifestations. It was first reported as a newly recognized disease by Moschcowitz[19] in 1925. The next report of the condition appeared in 1936 when Baeher, Klemperer, and Schifrin[2] clearly defined the syndrome and presented four additional cases. It has been described with increasing frequency in American medical literature during the past five years. An excellent review of the reported cases was made in 1952 by Barondess[3] and he added three new cases of his own. At present, the literature contains descriptions of about forty cases,[1-24] in only a small percentage of which was the diagnosis even considered antemortem. In 1952, Cooper, Stickney, Pease, and Bennett[10] reported two cases in which the diagnosis was confirmed antemortem by examination of aspirated bits of bone marrow. In most instances, the disease has occurred in young adult white women, although it has also been reported in men and in colored people.

The onset of illness is usually abrupt, although occasionally there has been reported a preceding period of vague ill health. The symptoms include malaise, weakness, fever, and frequently suggestions of an upper respiratory infection. Often there have been abdominal pains, anorexia, nausea, and vomiting. Anemia may be present at the onset or may develop during the course of the illness and is usually independent of the bleeding which accompanies the thrombocytopenic purpura. Transfusions have been of little benefit. Frequently jaundice and hyperbilirubinemia have accompanied the condition. Purpura and other hemorrhagic manifestations, such as melena, hematemesis, and hematuria, invariably have eventually been part of the picture. Aside from the hemorrhagic manifestations of the thrombocytopenic purpura, transient and bizarre neurological disturbances of almost any type have been distinctive clinical features. There may be headache, dizziness, delirium, confusion, drowsiness, and progressing coma. Transient paralysis or paresis are very common. The disease, in all reported cases, has been fatal, usually in from two to four weeks, varying from one week to three months. Engle[12] reported a case which had a partial remission of about one month's duration, but this is extremely rare.

In thrombotic thrombocytopenic purpura, the blood shows the typical manifestations of a hemolytic anemia, although the severity of the anemia and the rate of the hemolysis have varied greatly. The erythrocyte count and hemoglobin have dropped simultaneously, resulting in a normocytic, normochromic type of anemia. The mechanism of the hemolytic process has been carefully studied by Singer.[21,22] In the cases where the osmotic fragility has been reported, it was normal or increased. There has been no evidence of auto-immunization, transfused cells being destroyed as rapidly as the patient's own cells. The Coomb's test findings, when reported, have been negative. Reticulocytes have increased, and in many cases abnormal young erythrocytes of the normoblastic series have appeared in considerable numbers in the peripheral blood. Bone marrow in most patients in whom it has been studied has shown a moderate hyperplasia with normal megakariocytic activity. There has been, with rare exceptions, a uniformly persistent thrombocytopenia, accompanied by hemorrhagic phenomenon, and prolonged bleeding and clotting times.

The etiology of this condition remains as great a mystery today as it was to Moschcowitz in 1925. The possibility of an allergic reaction has been suggested,[15] but there is little evidence to support this theory. It has also been suggested that the condition may be a primary subendothelial, vascular lesion with secondary accumulation of platelets on the injured endothelial area.[15] The idea has also been advanced that this illness belongs to the so-called collagen group of diseases.

The hyaline thrombi have been described in

Presented before the Minneapolis Society of Internal Medicine, April 29, 1953.

almost every organ but, as Clough[9] pointed out, there is a surprising lack of information regarding the occurrence of lesions in the skin and skeletal muscles.

Treatment thus far has been useless. All cases have terminated fatally. Although there is no apparent evidence of hypersplenism in these cases, splenectomies were done in several instances and were ineffective. Final evaluation of the effect of splenectomy cannot be made at this time, however, particularly since most of the patients on whom the operations were performed were terminally ill at the time the surgery was done.[18] The results of treatment with ACTH, Cortisone, and various antibiotics have been unimpressive. Since there is no evidence, as mentioned above, of hyperimmune bodies, we should not expect benefit from ACTH and Cortisone as pointed out by Hagen.[17]

Report of Case

A forty-one-year-old white housewife was admitted to the Northwestern Hospital on October 9, 1952, primarily fearing that she was having a stroke.

For six months prior to admission, she had been working and living with painting and staining projects in her home. She had been very active in the painting work, handling paints, stains, and solvents. For about three months before the onset of acute symptoms, she had complained of weakness and exhaustion out of proportion to the amount of work she did. For a month prior to admission, she had been suffering from severe frontal headaches to which she had previously not been subject. She suffered from aches and pains in her legs. Because of these complaints, she had gone to a rest hospital for five days "to get a good rest away from her family." On October 8 her hemoglobin was 45 per cent. On the night of admission to Northwestern Hospital, she had experienced a transient aphasia and right-sided paresis.

Review of her past history revealed that the patient had had the usual childhood diseases without complication. She had always enjoyed good health and had been a very active, vigorous woman. She had an appendectomy in 1926, a tonsillectomy in 1946, and plastic surgery on the fallopian tubes in 1938. Menses started at age thirteen, and occurred every twenty-seven to thirty-five days with a normal flow for six days. Her systemic history was entirely negative and her routine medical examinations had always been reported as negative. When she was examined on March 11, 1952, there were no abnormal findings. At that time urinalysis was negative. The hemoglobin was 12.3 grams; erythrocyte count, 4,240,000; leukocyte count, 9,800 with 78 per cent neutrophils, 20 per cent lymphocytes, 1 per cent eosinophils, and 1 per cent monocytes. Erythrocyte sedimentation rate was 20 mm. in one hour. Stool was negative for occult blood.

Physical examination on admission to Northwestern Hospital revealed a well-developed, fairly well-nourished, white woman who appeared to be very apprehensive. Her skin and mucous membrane were pale. The eyes, including the fundi, were normal. The ears, nose, and throat were within normal limits. The tongue was normal. Examination of the neck revealed no adenopathy and no limitation of motion. Examination of the chest revealed no abnormality. The heart tones were normal; the cardiac rate was 100 per minute with a regular sinus rhythm. Examination of the abdomen revealed no palpable masses or viscera. There was no tenderness or rigidity. The abdomen was soft. Neurological examination was entirely negative. Blood pressure was 120/80. There were small hematomas on the shins of both legs. There were no petechiae noted.

On admission, the electrocardiogram was normal. The hemoglobin was 5.7 grams; erythrocyte count, 1,590,000, and the leukocyte count, 10,000 per cu. mm.

Shortly after admission, the patient complained of precordial pain. Because of this pain and low hemoglobin, she was given 1000 cc. of whole citrated blood intravenously during the first twelve hours following admission. On October 10, 1952, a bone marrow biopsy was done. Study of the bone marrow revealed a hematocrit of .5 per cent fat, 66.5 per cent plasma, 1 per cent myeloid-erythroid layer, 32 per cent erythrocytes. Study of the smears from the myeloid-erythroid layers showed a marked increase in the developing red cells. These were normoblastic cells. A mild increase in the plasma cells was also present and a normal number of megakariocytes was noted. There was no evidence of leukemia, tumor, or granulomata.

Further laboratory studies on October 10, 1952, revealed a hemoglobin of 8.4 grams; erythrocyte count, 2,400,000, and leukocyte count, 7,300. Differential study of the white blood cells revealed 73 per cent neutrophils, 24 per cent lymphocytes, 1 per cent monocytes, and 2 per cent eosinophils. The reticulocyte count was 14 per cent. The platelet count was 39,000. A urinalysis was normal. The bleeding time was 7 minutes 45 seconds; clotting time, 3 minutes. The prothrombin time was normal. The erythrocyte sedimentation rate was 27 mm. in 60 minutes.

Further laboratory studies within a few days after admission revealed normal blood urea nitrogen, normal cephalin cholesterol flocculation test, normal thymol turbidity test, no occult blood in the stool, and free hydrochloric acid in the gastric analysis. Coomb's test findings were negative on two occasions.

X-ray examination showed a normal chest, normal esophagus, stomach, and duodenum, following the ingestion of a barium meal, and a normal colon except for marked redundancy throughout. Repeated electrocardiograms showed no change and were essentially the same as those made in March, 1952, and February, 1951.

In spite of repeated transfusions (a total of 6,000 cc. of blood) during her hospital stay, the hemoglobin and erythrocyte count remained low. The platelet count varied between 18,000 and 52,000. The patient's red blood cell osmotic fragility was tested. Her cells began to hemolize at .54, and hemolysis was complete at .32.

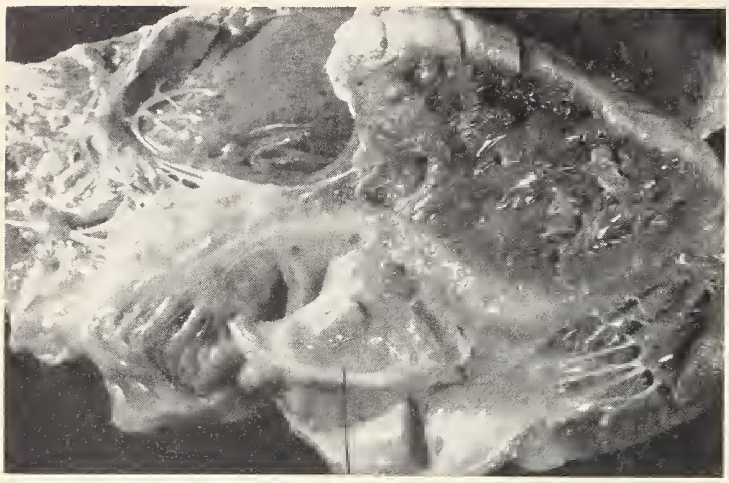

Fig. 1. Heart. Note the multiple petechial hemorrhages on the endocardial surface.

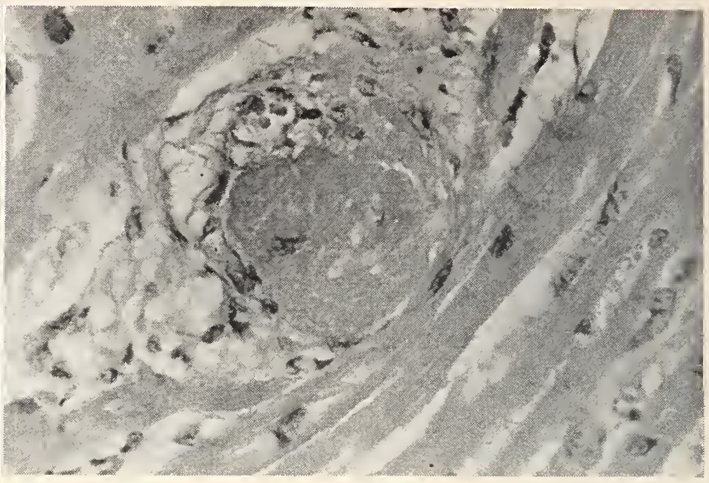

Fig. 2. Heart muscle with a typical lesion. Note the hyaline thrombus in the arteriole.

Control cells began at .46 and were complete at .34. There was no evidence of spherocytosis in any of the blood smear studies. The serum bilirubin was slightly elevated to 1.3 mg. Of this total, 0.12 mg. was direct acting. The thymol turbidity test showed 1 unit. Cephalin cholesterol flocculation test revealed one plus in twenty-four hours and 2 plus in forty-eight hours. On October 13, 1952, the quantitative urine urobilinogen was .9 units per 100 cc. of urine. Examination of the gastric contents on October 14, 1952, revealed normal free hydrochloric acid of 50 degrees and a total acid of 59 degrees.

On October 17, 1952, purpura was first noted on the patient's legs. On October 20, the Guaiac test on the stool was positive for the first time. On October 20, 1952, the possibility of thrombotic thrombocytopenic purpura was considered in the differential diagnosis. At this time Cortone was started by mouth, 25 milligrams four times a day.

On October 22, 1952, the patient started to menstruate with excessive blood loss. She also started to have bloody emesis at this time. Her liver became very tender and palpable at the costal margin. At times it was thought that the spleen could also be palpated in the left upper quadrant.

On October 25, 1952, the patient had repeated bloody emeses and was unable to keep the Cortone down. This drug was discontinued and ACTH, 100 mg., was given at once and 50 mg. every eight hours thereafter, intramuscularly.

During the evening of October 25, 1952, the patient was seen in consultation with Dr. C. J. Watson, who concurred in our diagnosis of hemolytic anemia and thrombocytopenic purpura and also with the possibility that this might be a thrombotic thrombocytopenic purpura. On October 27, 1952, the bone marrow slides were examined by Dr. Bennett and Dr. Stickney of the Mayo Clinic. While there were no thrombi visible in the sections we examined, Dr. Bennett thought there were some suggestive changes in some of the vessels, and suggested further bone marrow studies be made in an attempt to find the diagnostic lesions. The patient expired suddenly on October 28, 1952, nineteen days after admission to the hospital. During the nineteen days her temperature ranged from 98 to 100 degrees.

Autopsy (four hours after death) was performed and described by Dr. Frederick H. Lott.

General Appearance: The body was that of an adult white woman, measuring 158 cm. in length. Estimated weight was 125 pounds. The body was well developed and well nourished. Postmortem rigidity was present, and there was a mild postmortem lividity in the dependent parts. There was no edema or jaundice. The pupils were sound and equal. The ears and nose showed nothing of note. The teeth were in a good state of repair. The external genitalia showed evidence of bleeding, and the anus showed nothing of note. There were numerous small petechial hemorrhages over much of the body surface, many of which were secondary to injection. There was a well-healed lower abdominal scar which measured 16 cm. in length. There was a well-healed McBurney's scar measuring 12 cm. in length.

Abdominal and Thoracic Cavities: On opening the abdomen, the subcutaneous fat was found to measure 2 cm. in thickness. The peritoneal surfaces were smooth and shiny, and there was no excess fluid present. The appendix had been surgically removed. The liver extended 10 cm. below the xiphoid process and 7 cm. below the costal margin in the right midclavicular line. The diaphragm arched to the fourth rib on the right, and to the fourth intercostal space on the left. On opening the thorax, the lungs were found to be free and the pleural cavities empty.

Heart: The pericardial sac showed nothing of note save for a slight excess of clear amber fluid. The heart measured 13 cm. in width. Examination of the larger branches of the pulmonary artery showed no evidence of thrombi or emboli. The heart weighed 310 grams. The valves were normal in appearance. Examination of the coronary arteries showed nothing of note. The myocardium was somewhat flabby in consistency, and on cut section had a markedly mottled appearance, with small petechial hemorrhages separated by small greyish-yellow areas, which suggested fibrosis. This was extremely marked in both ventricles and in the interven-

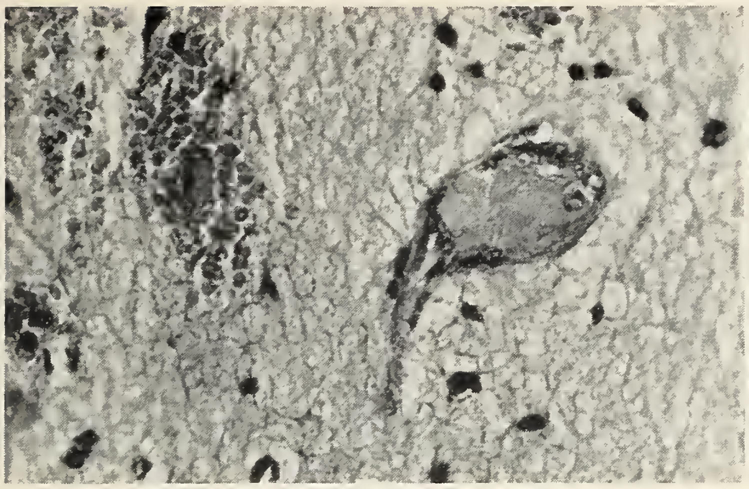

Fig. 3. Brain. Showing typical hyaline thrombi in the arteriole.

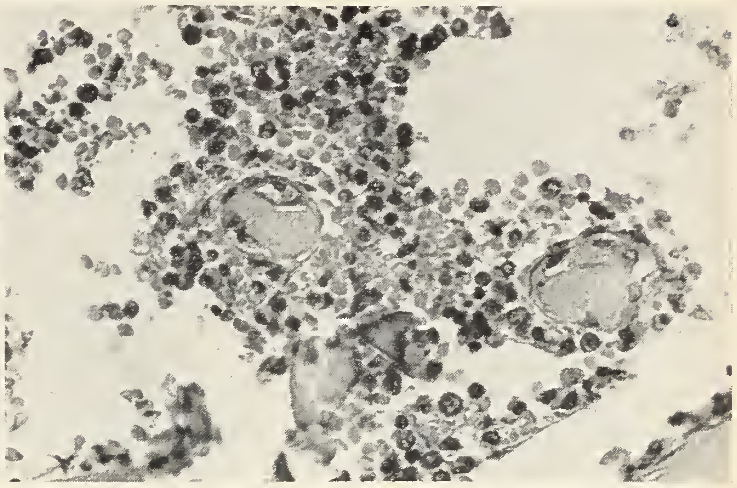

Fig. 4. Bone marrow. Showing two arterioles occluded by hyaline thrombi. This specimen was obtained at autopsy. The antemortem specimens unfortunately failed to show the lesions.

tricular septum. The petechial hemorrhages showed on the endocardial surface of both the right and left ventricles. The root of the aorta was free from atheromatous degeneration. The auricular appendages contained no thrombi.

Lungs: The right lung weighed 200 grams. The surface of the organ was smooth and crepitation was slightly reduced throughout. On cut section, the cut surface showed a very slight excess of blood and fluid, but there was no evidence of consolidation. The left lung weighed 180 grams. The surface of the organ was smooth, and crepitation was slightly reduced throughout. On cut section, the cut surface showed a slight excess of blood and fluid, but there was no evidence of consolidation.

Liver and Gallbladder: The liver weighed 1,900 grams. The surface of the organ was smooth and the edges sharp. On cut section, the cut edge everted, and the cut surfaces showed the markings to be indistinct. There was no gross evidence of darkening of the centers of the lobules. The gallbladder wall was normal in thickness. No stones were present. The common bile duct was patent.

Spleen: The spleen weighed 175 grams. The capsule wrinkled easily. On cut section, the edge everted and the cut surface was red in color. The pulp was soft in consistency. The splenic corpuscles were barely visible.

Pancreas and Adrenals: The pancreas and adrenals showed nothing of note.

Kidneys: The right kidney weighed 150 grams. The capsule stripped easily, leaving a smooth surface. On cut section, the cut edge everted, and the cut surfaces showed the markings to be indistinct. There was no evidence of atrophy of the cortex. The pelvis and ureters showed nothing of note. The left kidney weighed 165 grams. It showed a picture similar to that of the opposite organ.

Bladder and Genital Organs: The bladder contained a few cubic centimeters of a clear yellow fluid, but the bladder mucosa showed numerous hemorrhagic areas. The uterus was normal in size, and, on cut section, contained a small amount of clotted blood. The endometrium was smooth and the cervix showed nothing of note. The fallopian tubes were free and the fimbriated ends appeared patent. On cut section, they were normal in caliber. The ovaries were normal in size, and, on cut section, showed nothing of note.

Abdominal Aorta: The abdominal aorta showed a very mild degree of atheromatous degeneration.

Gastrointestinal Tract: The gastrointestinal tract showed numerous petechial hemorrhages.

Head: On opening the head, the scalp and calvarium were found to be normal in appearance. Examination of the brain showed approximately twenty petechial hemorrhages measuring up to 2 mm. in diameter in the cortex of the brain. These were most pronounced on the right side. The entire brain substance was slightly softened, but otherwise there was no evidence of gross hemorrhages, tumor, or softening. The pituitary gland was normal in appearance.

Microscopic examination showed innumerable hyaline thrombi within the capillaries and arterioles of all the major organs including the bone marrow. These were especially numerous in the myocardium and brain. Associated with these thrombi were scattered small hemorrhages which were surrounded by beginning degeneration of the myocardium and brain. The balance of the sections showed nothing of note.

Diagnoses: Thrombotic thrombocytopenic purpura, with petechial hemorrhages in the heart and brain.

Discussion

While this disease is undoubtedly rare, it is probably more common than the number of cases which have been reported since 1936 would lead one to believe. Diagnosis is probably missed because of our unawareness of the syndrome. We feel that we are justified in reporting this case in order to bring the syndrome to the attention of a greater number of physicians, pointing out again the salient diagnostic features: transitory bizarre neurological disturbance, thrombocytopenic purpura, and hemolytic anemia. Awareness of the syndrome may facilitate earlier diagnosis of the condition and bring about a better understanding of the etiology, pathogenesis, and treatment.

Summary

1. A case of thrombotic thrombocytopenic purpura with clinical and pathological findings is reported.

2. The clinical picture is manifested by a fulminating thrombocytopenia, hemolytic anemia, and transient focal neurological abnormalities.

3. The postmortem examination is characterized by widespread hyaline thrombotic lesions involving the arterioles and capillaries. The exact nature of these thrombi has not been determined.

4. Its etiology is unknown, and to date all reported cases have been fatal.

5. The importance of antemortem studies has been pointed out.

MALNUTRITION

It is well known that hookworm disease, malaria, and tuberculosis are intimately related to malnutrition in many persons who suffer from these diseases, but whether or not the relationship is causal defies affirmation except in certain individual situations. The sufferer of malaria or hookworm disease may be malnourished because of anemia that reduces his productive and earning capacity and therefore his ability to provide for his food needs; or the malnourished person, as a result of diminished resistance, may fall an easy victim to such diseases. Whatever may be the relationship, it is clear that the well-being of the individual is compromised by malnutrition as well as by certain specific diseases.—Institute of Inter-American Affairs, Public Health Reports, November, 1953.

HYPERSPLENISM: LEUKOPENIC-THROMBOPENIC SYNDROME

Report of Two Cases

HAROLD E. MILLER, M.D., and FREDERICK H. K. SCHAAF, M.D.
Minneapolis, Minnesota

LEUKOPENIA with splenomegaly usually presents a troublesome diagnostic and therapeutic problem. In 1924, Felty[4] described the syndrome of chronic arthritis associated with splenomegaly and leukopenia. In 1932, Hanrahan and Miller[5] reported the first case of splenectomy for Felty's syndrome. In 1939, Wiseman and Doan[10] described a syndrome which they called "primary splenic neutropenia." This syndrome was characterized by severe neutropenia of the peripheral blood, splenomegaly, and hyperplasia of the myeloid elements of the bone marrow. The mechanism by which these pathological changes take place has been and still is a much disputed point. One school of thought holds that the cells are removed by abnormal phagocytosis by the hypertrophied reticulo-endothelial cells of the spleen.[3,11] Another school contends that the condition is due to an unusual inhibitory effect on the bone marrow of a hormonal substance secreted by an overactive spleen.[2] Both groups agree that these interpretations are at the present time highly theoretical. In 1946, Doan and Wright reported hypersplenism secondary to other chronic diseases of the spleen.[3] These cases show the same clinical picture as those described in the earlier paper as primary splenic neutropenia by these investigators. A survey of the available literature revealed many cases which fit the primary and secondary syndrome. In 1948, Smith and McCabe[8] and in 1950, Rogers and Langley[6] reported examples with hypoplasia of the bone marrow with complete recovery of hematopoiesis following splenectomy. Since Doan and Wright's publication, several cases have been reported which may be classified as "secondary hypersplenism," which apparently benefited from splenectomy. The problem then becomes: Is there actually a primary splenic neutropenia or is the syndrome a symptom of a disease process in which the etiological factor is not recognized?

It is the purpose of this paper to report two cases of apparent hypersplenism, one of which presents an unusual bone marrow morphology which we believe is unique and instructive, and the other demonstrates a portal hypertension with secondary hypersplenism.

Case Reports

Case 1.—A white woman, aged fifty-four years of age, was referred to the authors by Dr. H. Kath of Wood Lake, Minnesota. Her principal complaints were weakness, fatigue, 42-pound weight loss, and repeated bouts of chills and fever over an eight months' period.

Physical examination showed a thin white woman who appeared to be listless and chronically ill. Her temperature was 100.6°, the pulse 102, and the blood pressure 122/82. The spleen was palpable 6 cm. below the left costal margin. The liver was not palpable.

Laboratory studies showed a leukopenia and neutropenia. The range of the leukopenia is shown in Graph A. Examination of the peripheral blood smear showed 6 per cent immature cells, which were interpreted by various pathologists as atypical immature myeloid cells of the type found in leukemia. Although there was no clinical evidence of leukemia, a bone marrow study done on May 23, 1947, was characteristic of a myeloid leukemia. Marrow preparations and the peripheral blood smears, obtained on June 1, 1947, were then sent to two hematologists, Dr. Hal Downey, University of Minnesota, and Dr. E. M. Schleicher, Minneapolis General Hospital, who independently interpreted the immature cells in the peripheral circulation as non-malignant reticulo-plasma cells and the myeloid hyperplasia of the marrow as myeloid maturation arrest rather than myeloid leukemia. Figure 1 shows a reticulo-plasma cell in the peripheral blood. In addition to the myeloid hyperplasia, the marrow sections showed several epithelioid granulomas, an example of which is shown in Figure 2. Plasma cells and eosinophils formed a loose cuff about the epithelioid structures. No giant cells were seen. We have not been able to find a paper which reports such a lesion in the bone marrow in a case of hypersplenism. This granulomatous lesion was somewhat similar to those described by Schleicher in herpes zoster.[7] Demonstrations of these granulomatous lesions led us to believe that we were dealing with a virus infection superimposed upon or causing the hypersplenism.

On July 10, 1947, in spite of our patient's serious condition and the presence of high fever, it was decided that a splenectomy should be carried out. An 800 gram spleen was removed by Drs. O. J. Campbell and N. C. Plimpton. Microscopic examination of many spleen sections revealed a rather severe reticulum hyperplasia, although no proliferation of malignant cells was seen. Many sinusoids were open and somewhat congested with red blood cells and contained from a few to many reticulo-plasma cells morphologically identical to those seen in the peripheral blood. Since only a few of these reticulo-plasma cells were seen in the bone marrow preparation, it is believed that the majority of cells were proliferated in the spleen.

Bone marrow obtained one month after the splenectomy

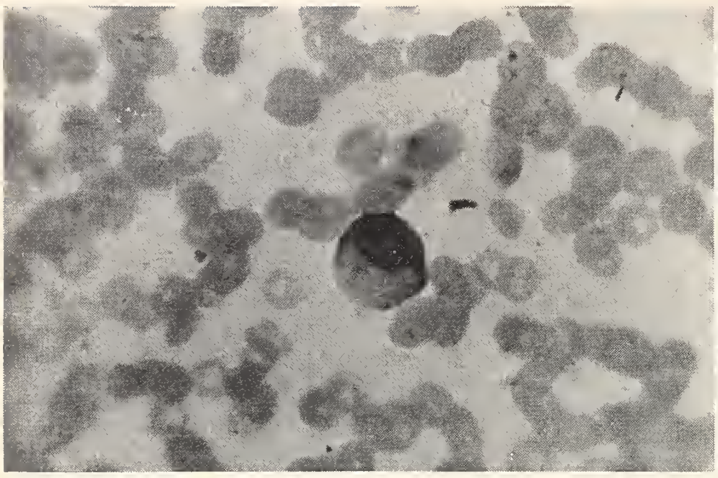

Fig. 1. Blood smear showing a reticulo-plasma cell. Six per cent of the leukocytes were this type of cell.

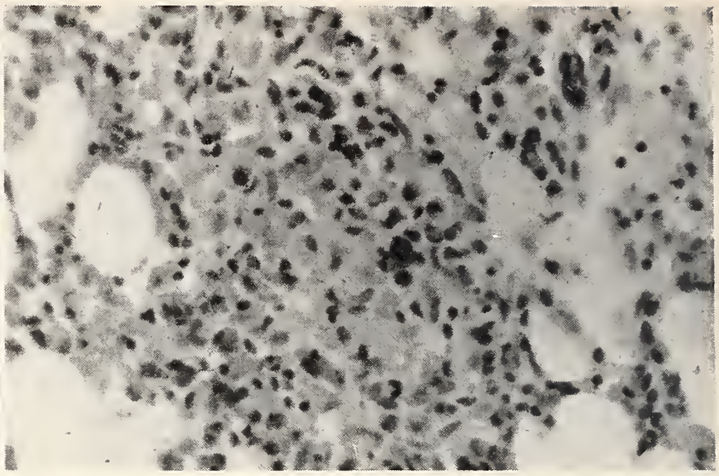

Fig. 2. Epithelioid granuloma in the bone marrow preparation.

showed none of the granulomas previously described, and normal maturation of the myeloid cells was found. Bone marrow aspiration on April 4, 1949, two years after the surgery, showed a normal marrow. The patient made an uneventful recovery and six years postoperatively is enjoying good health. We feel that this patient had hypersplenism without thrombocytopenia. The hypothesis may be advanced that the leukopenia which was corrected following splenectomy may have been in part the result of a chronic infection. We believe that this case points out the necessity of examining sections of the bone marrow as well as smears in cases of hypersplenism for conclusive interpretation of the character of myeloid hyperplasia.

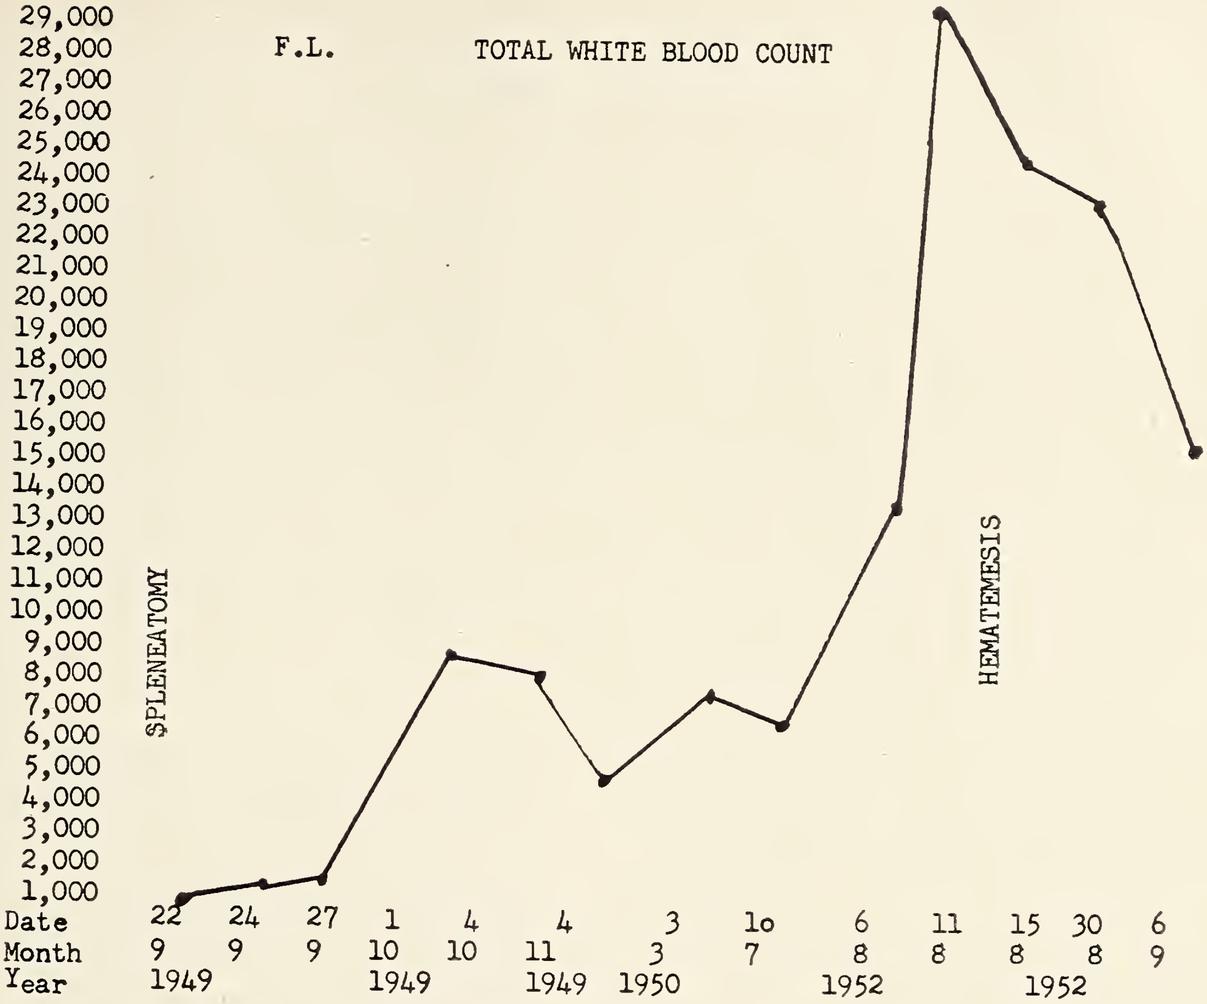
Case 2.—A fourteen-year-old boy was admitted to the Northwestern Hospital on December 23, 1949, referred by Dr. E. A. Thayer and Dr. O. E. Wandke of Fairmont, Minnesota. The patient's present illness dated back to September 14, 1949, at which time he had fractured his left forearm while playing football. The fracture had been reduced satisfactorily and the patient returned to his home. On September 17, 1949, he had a hematemesis, losing approximately one quart of blood. He was hospitalized and given two blood transfusions. It was then discovered that he had a marked leukopenia and a splenomegaly. A review of the patient's past history revealed that he had the usual childhood diseases without complications. He had a fracture of the left forearm at age four which healed uneventfully. In October, 1948, he had had a hematemesis but otherwise had enjoyed perfect health. He had been an active child and since entering high school had taken part in athletics.

Physical examination on admission to the hospital revealed a well-developed, fourteen-year-old boy who was pale but otherwise did not appear to be in any distress. Examination of the abdomen revealed the spleen to be palpable 5 inches below the umbilicus. The spleen was hard but not tender. There were no further remarkable physical findings. The left arm was in a well-fitting plaster cast. Laboratory studies on admission to the hospital revealed the patient had a hemoglobin of 7.6 grams; an erythrocyte count of 2,560,000; a leukocyte count of 950 with 31 per cent neutrophils, 64 per cent lymphocytes, 3 per cent monocytes, and 2 per cent eosinophils. His reticulocyte count was 4.6 per cent; the platelet count was 10,000. The bleeding time was 3 minutes and 50 seconds; the clotting time, 5 minutes and 30 seconds. His sedimentation rate was 22 mm. in one hour. The stool was positive for occult blood. The total serum protein was 5.3 grams with 3.4 grams of albumin and 1.9 grams of globulin. The serum bilirubin level was 1.4 mg. per cent. The urinalysis was negative. Bone marrow was obtained by sternal aspiration on September 23, 1949; and smears, imprints, and histological sections were prepared. The preparations showed a marked myeloid hyperplasia with maturation arrest.

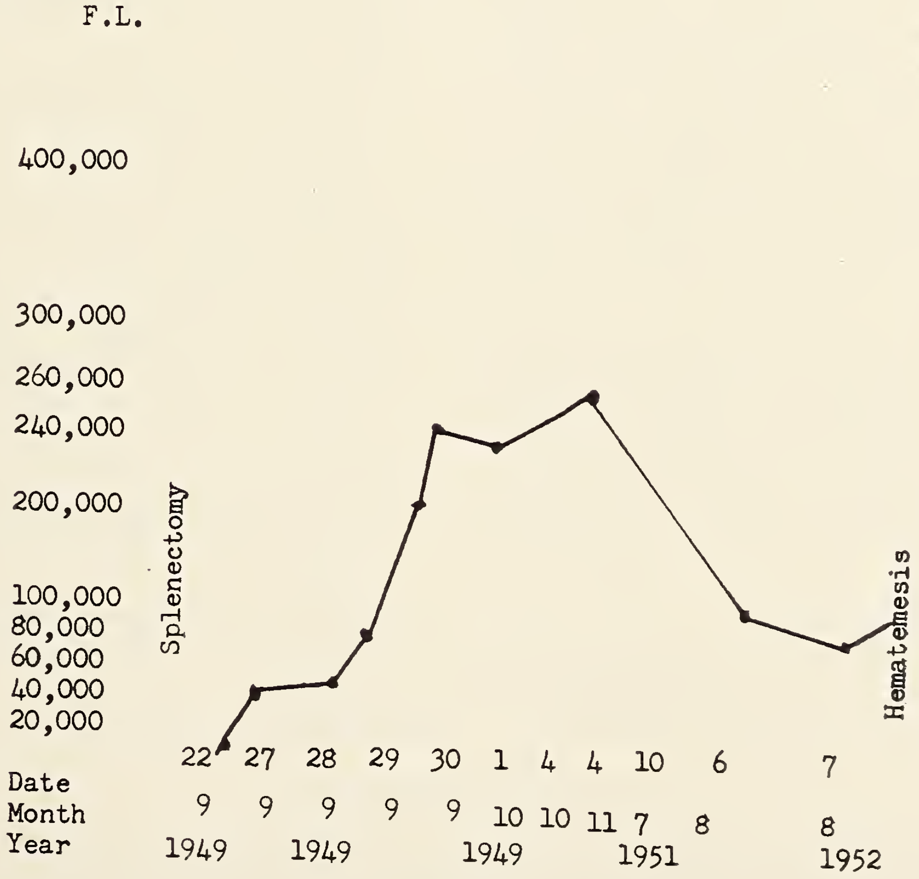
On September 28, 1949, a 1,247 gram spleen was removed by Dr. M. C. Nelson. On gross examination, the spleen was not considered remarkable. The microscopic examination disclosed the sinusoids to be small and not congested. An insignificant amount of fibrosis was present. The lymphoid follicles were relatively small and widely spaced. There was an occasional hemorrhagic area ranging from one to two mm. in diameter. There was nothing seen to suggest a malignant lymphoblastoma or any specific disease.

Postoperatively, the patient's course was uneventful. His hematological response is shown in Graphs 1 and 2. On October 4, 1949, his hemoglobin was 16.8 grams. His erythrocyte count was 5,290,000. His leukocyte count was 8300 with 74 per cent neutrophils, 23 per cent lymphocytes, and 1 per cent monocytes. The platelet count was 232,000. His urine remained normal. The patient was seen again on November 4, 1949; and physical examination was entirely negative. On March 3, 1950, he was seen again, at which time his hemoglobin was 15.6 grams; red blood cell count was 4,560,000; white blood cell count was 8000; and the red blood cell sedimentation rate was 14 mm. in one hour. Differential studies of the blood at this time showed 23 per cent neutrophils, 76 per cent lymphocytes, and 1 per cent eosinophils.

From March 3, 1950, until August 4, 1952, this young man was well and was working as a truck driver. At 11:30 P.M. on August 4, 1952, he was awakened by an emesis of a large quantity of blood. He was taken to the local hospital, where he was given blood transfusions; and then because the hematemesis recurred he was



Graph 1.



Graph 2.

brought to the Northwestern Hospital at 3 A.M. on August 6, 1952. Physical examination on admission to the hospital was entirely negative. The hematemesis continued, necessitating repeated blood transfusions. Eighteen hours after admission, x-ray examination following a barium meal revealed a marked degree of varices extending from the aortic arch to the distal end of the esophagus. Laboratory studies revealed an anemia but no other diagnostic findings. Liver function tests and bone marrow studies were normal.

The hematemesis persisted in spite of balloon tamponage; so, although the patient's condition was poor, an attempt to do a venous shunt to relieve the portal hypertension was made on August 16, 1952. The pressure was measured in a large vessel in the omentum and found to be 385 mm. of blood. The veins in the omentum and on the peritoneum were large and tortuous. The esophagogastric junction was exposed and all the veins from the diaphragm and about the junction were clamped and ligated. The esophagus was pulled down about 4 cm. and packed around its entire circumference with gelfoam. The patient's condition was such that further exploration and shunting procedures were deemed unwise. A liver biopsy was taken and reported as normal.

On August 30, 1952, laparotomy was again undertaken with the plan in mind to establish a portacaval or a splenorenal shunt. The splenic vein was exposed by Blakemore's technique[1] and found to be completely thrombosed, as was the portal vein. In place of the portal vein were a few collateral venus channels which were small and very friable. None of these veins was considered suitable for a shunting procedure.

Following this second operation the hematemesis and melena subsided, and the patient was discharged by ambulance to the hospital in his home town on September 6, 1952, one month after admission on August 6, 1952. From August 4, 1952, to September 6, 1952, he received a total of 71 pints of blood. His hemoglobin varied from 5.3 grams to 16.8 grams and was 13.4 grams at the time of discharge. Leukocyte counts, differential studies, and platelet counts were all normal. After September, 1952, he had three massive gastrointestinal hemorrhages, each necessitating several transfusions. He had a massive hemorrhage in June, 1953, and expired. An autopsy was refused.

It was our original impression that this patient had a hypersplenism with leukopenia and thrombocytopenia preceding his first hematemesis in October, 1948. Now we wonder if this hematemesis and the splenomegaly may have been due to portal hypertension, and whether the portal hypertension should not have been relieved at the time of the original operation.

Summary

Two cases of hypersplenism are presented—one patient had anemia and neutropenia and the other anemia, neutropenia, and thrombocytopenia. Case 1 had granulomatous lesions in the bone marrow, suggesting a secondary type of hypersplenism. Case 2 simulated a primary portal hypertension with secondary hypersplenism. This second case demonstrated the value of the warning made by Blakemore and Fitzpatrick[1] and earlier by A. O. Whipple,[9] that when a splenectomy is attempted the surgeon should always look for portal hypertension and, if possible, determine its cause. He should be prepared to do a splenorenal or a portacaval shunt if it is indicated. These cases lead us to speculate that perhaps, as more information accumulates, all the cases of so-called primary hypersplenism will prove to be secondary to some other primary condition.

The most important elements in the diagnosis of cancer remain those natural attributes of the physician—he must see, hear, and feel the manifestations of malignant processes before utilizing his store of complex tools and methods.

FLUID REGULATION IN NEPHRITIS AND NEPHROSIS OF CHILDHOOD

EDMUND C. BURKE, M.D.
Rochester, Minnesota

THE KIDNEY constitutes the main organ for the regulation of fluids and electrolytes. By an active process of filtration, absorption and excretion the kidney defends the normal chemical pattern of the plasma. The maintenance of body stores of water, the acid-base ratio of the blood and tissue cells and the elimination of products of metabolism cannot continue indefinitely in the face of chronic renal disease.

All efforts in fluid and electrolyte therapy for renal disease are based on the assumption that renal function is temporarily or partially inadequate. There is, as yet, no artificial means to maintain indefinitely, an individual with progressive renal failure, recent developments in the artificial kidney notwithstanding.

The efforts of Gamble[4,5] to acquaint members of the medical profession with the fundamental concepts of fluid and electrolyte metabolism are outstanding among those of many researchers in this field. I shall draw upon his contributions in this consideration of the requirements of children with renal disease. What is written here will be confined to a few physiologic aspects of fluid and electrolyte metabolism, on which can be based a rational course of treatment as regards administration of salt and water.

The glomerulus, by a process of filtration, produces a protein-free ultrafiltrate of plasma. The volume of filtrate produced daily approximates 180 liters. Roughly 25 per cent of the cardiac output passes through the glomeruli at any given time. It is generally agreed that the rate of filtration by the glomeruli is relatively constant.

Urea is one of the most important substances removed from the plasma by glomerular activity. Glomerular filtrate has the same acid-base ratio as plasma; that is, a pH of 7.4.

As glomerular filtrate courses past the cells of the renal tubules all but about 2 liters are reabsorbed. In the renal tubules the pH changes from 7.4 to acidity or alkalinity as dictated by the state of metabolic activity and renal function. The limit for acidity of the urine is a pH of 4.8 while the limit of alkalinity of urine is a pH of 7.8.

Two mechanisms for acidification of the urine and conservation of base are employed in normal renal function. The first of these functions consists in substitution of a hydrogen ion supplied by the renal tubule cell for a sodium or potassium ion in the tubular fluid. Glomerular filtrate contains a phosphate with two sodium ions. By substituting a hydrogen ion for a sodium ion half of the base is conserved. The monosodium phosphate is an acid salt and thus tubular fluid is acidified. The degree of acidification may be determined by titration with tenth normal sodium hydroxide to a pH of plasma. The resultant value is usually referred to as "titratable acidity." Above a pH of 7.4, therefore, there would be no titratable acidity, by definition.

A second mechanism for economy of base involves the production of ammonium by tubule cells. The operation of these two adjustments effectively compensates for the excretion of large amounts of acid substances without the depletion of body stores of base. Figures 1 and 2 show quantitatively the adjustment of the production of ammonium and titratable acidity to cover the excretion of acid radicals in the urine.

It is possible to foresee the consequences of chronic renal disease if consideration is given the aforementioned facts. Damage to the glomeruli results in failure to excrete urea, phosphates, sulfates and organic acids. The plasma therefore has a relative deficiency of base; a state of azotemia and acidosis is the consequence. When the renal tubular function is impaired the tubules cannot continue to conserve base and then it becomes necessary for larger amounts to be excreted to maintain the reaction of the urine within the physiologic range. The renal tubules also lose the ability to reabsorb water and stores of body water are rapidly lost.

There is yet another feature of tubular failure which produces distortion of fluid and electrolyte balance. Due to the loss of concentrating ability of the renal tubules as the load of substances to be excreted from the plasma has become greater,

---

From the Section of Pediatrics, Mayo Clinic.
Read at the meeting of the Southern Minnesota Medical Association, Mankato, Minnesota, September 14, 1953.

removal of the load demands removal of larger volumes of water.

One sees then, that in advanced renal disease large volumes of urine of low specific gravity, and of alkaline reaction, are excreted.

Alkalosis is an unusual occurrence in renal disease, acute or chronic; therefore it merits no special consideration at this time.

The minimum amount of water required to form urine depends on the amount of substance or solute to be excreted. This need for water is usually defined as the renal obligatory water requirement. In children the renal obligatory need varies from 200 to 500 cc. per day. This requirement must be met even in starvation or thirsting and if not provided for by intake the need will be met by metabolism of the body stores of protein. Oliguria, anuria, or dehydration and death are the consequences of inadequate available water for renal function. In figure 3 the relationship of urinary volume to load of solute is depicted. On the right side of the graph the volume of water for intake and output is indicated for various routes.

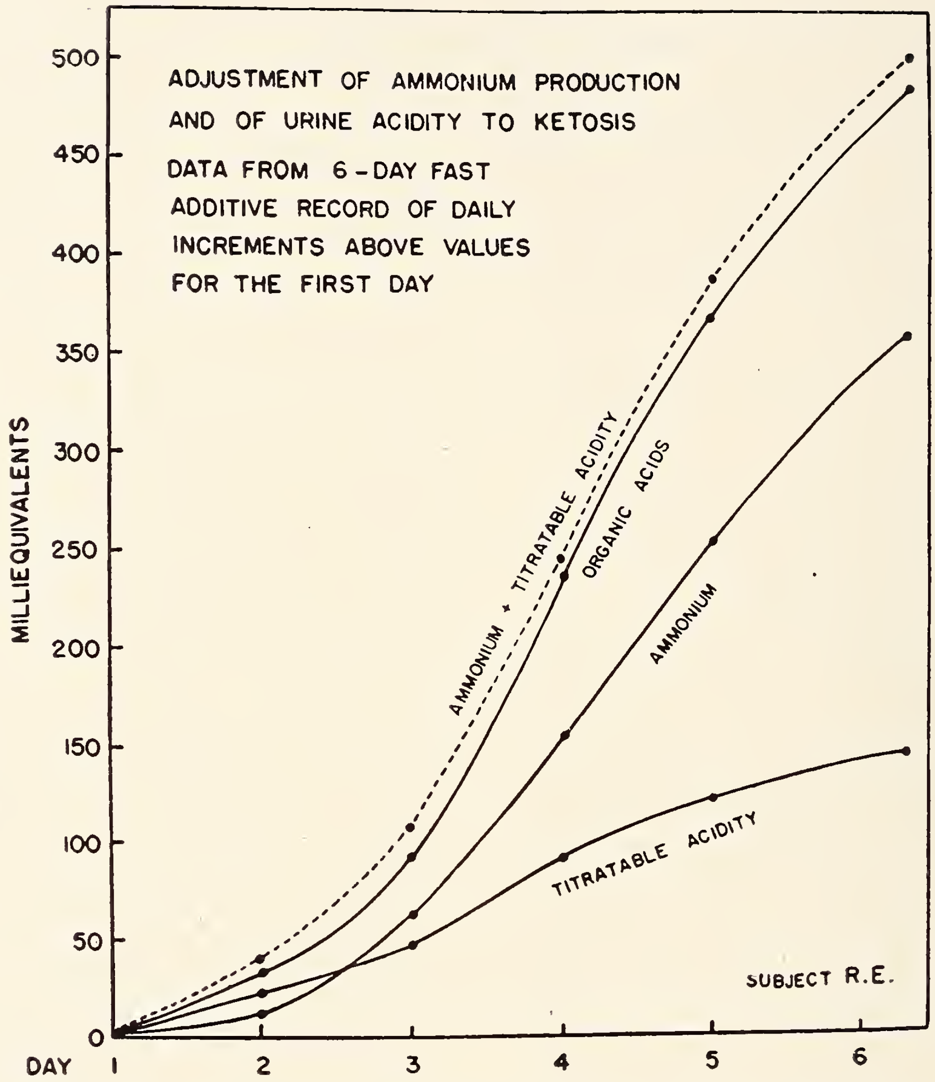

Fig. 1. Reprinted from "Companionship of Water and Electrolytes in the Organization of Body Fluids" by J. L. Gamble[5] with permission of the author and of the publishers, Stanford University Press. Copyright 1951 by the Board of Trustees of the Leland Stanford Junior University.

To the daily water requirement for renal function must be added the volume of water lost through the lungs and skin. This is designated as the insensible loss of water. The 24-hour water requirement for children varies from 150 cc. per kilogram for the infant to 75 cc. per kilogram for the older child. Fever and high environmental temperature increase the daily water requirements. The importance of the consideration of water requirements and renal function will become evident in discussion of acute and chronic states of kidney disease.

Acute Nephritis

The most common form of renal disease in children is acute hemorrhagic nephritis or glomerulonephritis. Varying degrees of severity of the disease are known to occur but in general the recovery rate approaches 98 per cent.[6] Two-thirds of the cases of acute nephritis in childhood occur under the age of 7 years. The disease is rare in infancy. Most clinicians agree that there is a distinct difference in the prognosis for acute nephritis as it occurs in adults. Similarly, the nephrotic syndrome is a significantly different disease in the adult than it is in children.

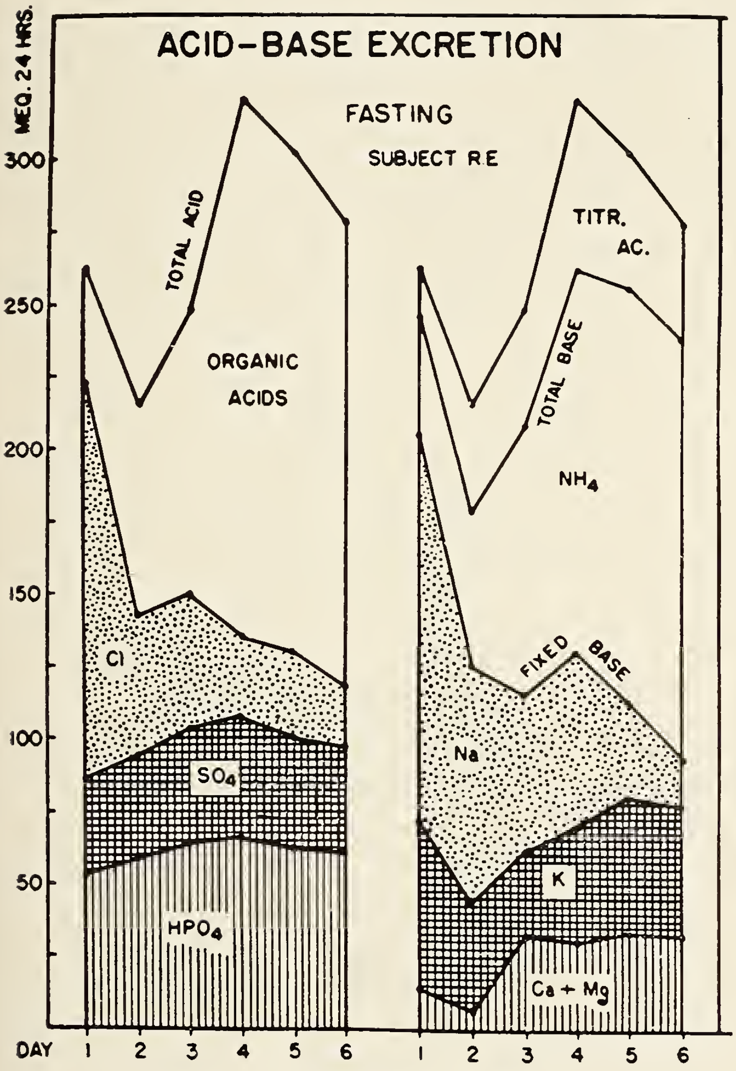

Fig. 2. (For legend, see Fig. 1.)

Generally, the onset of acute nephritis follows a streptococcus infection and is heralded by hematuria. In the average case of acute glomerulonephritis there is no need for limitation of the intake of fluid, salt or protein; therefore the concern here will be with only two complications of acute nephritis associated with severe manifestations which demand special therapeutic considerations.

The first of the two types is referred to as “hypertensive encephalopathy.” In this rather dramatic and acute illness the child suddenly has a convulsion. The blood pressure is markedly elevated and the child is comatose or confused. The concentration of blood urea usually is not elevated.

Prompt treatment to prevent convulsions and to reduce the hypertension is essential. Intramuscular administration of a 50 per cent solution of magnesium sulfate is effective as an anticonvulsant. The dosage is usually 0.2 cc. per kilogram of body weight, given every four hours until the adequate response in blood pressure is noted.

Magnesium relaxes arteriolar spasm to lower the blood pressure. Ettledorf and Tuttle have shown that it also increases the glomerular filtration rate, which is reduced in the acute phase of nephritis. The toxic effects of magnesium manifested by respiratory depression and narcosis can be counteracted by intravenous administration of calcium gluconate.

There is little need for rigid restriction of oral intake of fluids but the children frequently are comatose, in which case they require parenteral administration of fluid. Intravenous injection of fluid should be limited to an amount equivalent to the urinary output plus the estimated insensible loss. Sodium chloride should not be given, either intravenously or orally. The hypertensive phase usually abates within seven days and as a rule recovery is complete.

In the second group of patients the blood pressure may be found to be normal but oliguria and azotemia are apparent. The patients represent a small percentage of the total cases of acute nephritis but they are acutely ill and treatment is a special consideration. Oral intake of fluids may be limited somewhat and ingestion of salt should be restricted. As was mentioned previously, when oliguria or anuria is encountered intravenous administration of solutions must be restricted to replacement of daily losses from the skin, lungs and kidneys.

It used to be common practice to “flood” the anuric patient with parenterally given fluids to induce formation of urine and alleviate azotemia. The fallacy of this is obvious. Administration of an excess of fluid can only result in edema, dilution of the plasma electrolytes and aggravation of a serious clinical syndrome. Occasionally rapid administration of fluid results in convulsions. This occurrence has been termed “water intoxication.”

Presumably, cerebral edema is the cause of the convulsions.

The value for serum potassium may rise sharply in anuric states to produce signs of potassium toxicity of hyperkalemia. The concentration of serum potassium is typically more than 5 mEq. per liter in this state and an electrocardiogram shows characteristic shortening of the Q-T interval, with marked peaking of the T wave. If sodium chloride in water is administered cautiously the effects of hyperkalemia or hyperpotassemia may be prevented.

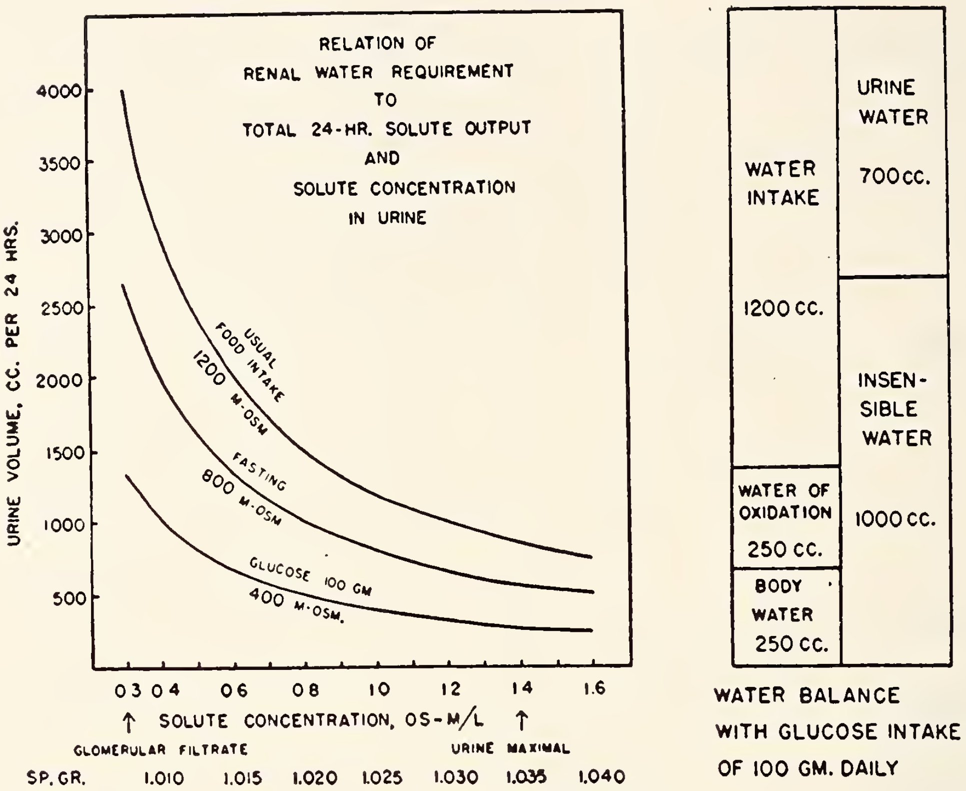

Fig. 3. (For legend, see Fig. 1.)

Chronic Nephritis

Contrasted with acute nephritis, edema in chronic nephritis is exceedingly rare. The chronic phase of nephritis is unusual in children and there are differences of opinion as to the relationship of the acute nephritis of childhood to chronic nephritis in adults. Most likely there are rare cases of chronic nephritis of adults attributable to acute nephritis which occurred in childhood.

Edema[9] in chronic nephritis usually is found only as an accompaniment of cardiac failure. Proper treatment with digitalis is indicated, but restriction of the intake of salt must be cautious.

Characteristically, the patient with chronic nephritis excretes large volumes of dilute urine which has a low specific gravity and an alkaline reaction. The large output of urine is the result of diseased renal tubules. The glomeruli also are damaged; hence, azotemia is produced.

Tubular deficiency produces excessive loss of stores of fixed base; that is, sodium, potassium, calcium and magnesium. The tubule cell is unable to substitute hydrogen ions for base ions and an alkaline urine results. The production of ammonium by the tubule cells is deficient; therefore, large amounts of base are excreted with the acid radicals (sulfate, phosphate and organic acids).

The titratable acidity is absent in an alkaline urine with a pH above 7.4. The tubules also have been impaired to the degree that reabsorption of water is altered and the result is polyuria.

Gamble maintains that a high level of blood urea is protective to a certain extent in that this extra load of solute demands an added output of water for its removal. Oliguria or anuria following trial with the artificial kidney for removal of urea and azotemic products from the plasma has been commonly observed.

Loss of base in the urine over a prolonged period results in the mobilization of calcium from bone with consequent demineralization of the skeleton. Renal rickets, though not a common accompaniment of this type of tubular disease, can occur and tetany may be noted.[2]

Albuminuria contributes to the possibility of tetany since calcium is in part protein-bound. Excessive treatment with alkali to correct the acidosis of renal disease may also produce tetany because of the reduction of available ionized calcium in an alkaline medium.

The treatment of chronic nephritis therefore consists in the provision of an adequate intake of water. Alkalinizing treatment with Shohl's solution (citric acid, 190 cc.; sodium citrate, 90 cc.; water sufficient to make 1,000 cc.), is indicated. The usual oral dosage of this mixture is 1 ounce four times a day.

Calcium may be supplied by a large intake of milk. Very little calcium will be absorbed from the intestine if any calcium salt other than calcium lactate is used. To be effective, calcium lactate must be dissolved in boiling water and cooled.

Some clinicians advocate the use of antacids on the theory that antacid blocks the absorption of phosphates from the gastrointestinal tract. Caution must be used in prolonged use of antacids, and occasional determinations of the pH or carbon dioxide content of the serum should be made to avoid gross disturbances of electrolytes.

While death from renal insufficiency is the usual outcome of chronic nephritis, many years may be added to the patient's life by careful management of the disease.

Nephrotic Syndrome

The term "lipoid nephrosis" has been supplanted by the term "nephrotic syndrome." The latter is preferable because the clinical course of each case is similar to that of every other. Pure or lipoid nephrosis is less commonly encountered and supposedly is not accompanied by hematuria or azotemia. The diagnosis "nephrotic syndrome" applies to cases with or without microscopic hematuria, casts, albuminuria and mild azotemia.

Typically, the onset of the nephrotic syndrome is insidious, with edema of the periorbital region or of the ankle as the presenting symptom. From the onset the syndrome progresses to massive edema, ascites, hypoproteinemia, oliguria and anemia. Remissions and exacerbations are the rule and the predisposition to intercurrent infection is well known.

Kohn and Obrinsky's series of nephrotic patients has been followed over a period of twenty-six years. This series included fifty-seven children of whom thirty-six died. Most of the fatalities occurred before the advent of satisfactory treatment with sulfonamides and antibiotics.

In a more recent survey of cases by Philips, Calvin and Kagan, twenty-nine patients were followed from 1944 to 1950 and a more encouraging report is presented. These authors advanced the idea that the survival of twenty-three of the twenty-nine patients was primarily due to the prevention of infection. Four of the six children who died succumbed to bronchopneumonia. The importance of effective use of antibiotics and chemotherapy is apparent.

The physiologic alterations in the nephrotic syndrome are loss of protein through the damaged glomerular basement membrane, a decreased glomerular filtration rate and excessive retention of salt and water by the renal tubules.

In the past few years, significant developments in the treatment of the nephrotic syndrome have resulted through the use of corticotropin (ACTH) and cortisone. While foremost authorities in study of the nephrotic syndrome make no claim that these potent hormones cure the disease, there is increasing evidence that corticotropin and cortisone are effective in prolonging remissions. From this clinical observation has come careful speculation that the ultimate outcome will be a higher incidence of complete recovery.

In the past several years, the general attitude of pediatricians has changed from one of "let nature take its course" to one of more active treatment of the nephrotic syndrome. Dextran, a polysaccharide of high molecular weight and polyvinylpyrolidon (PVP) also have been employed as effective means of producing diuresis.

Metcoff and associates have advocated a ten-day course of corticotropin in a dosage of 150 mg. per square meter of body surface per day to be given in four divided injections to effect diuresis. Approximately 70 per cent of children so treated will undergo diuresis following this program. On a second, later trial diuresis will result in an additional 13 per cent. Other investigators have advocated oral administration of cortisone for several days a week for a period of six to eight weeks following diuresis.

The electrolyte pattern of the nephrotic syndrome has been well defined by the studies of Metcoff and associates. Before diuresis with corticotropin, the concentration of sodium, potassium, chlorine and carbon dioxide in the serum were normal. Following diuresis, no change of significance occurred except for a minor rise in serum sodium and a slight fall in serum potassium. Extensive studies of renal function showed that the diuresis accompanied significant improvement in the glomerular filtration rate and in renal tubular function. A few patients experienced gross disturbance of electrolytes which demanded prompt treatment of alkalosis. Several other patients suffered infections. The intake of fluid or salt was not restricted during treatment. Excessive salt was not permitted in the diet, however.

In the cases of Metcoff and associates, when sodium was needed potassium also was administered despite the lack of excessive loss of potassium during diuresis.

Those with whom I am associated believe that definitive treatment for patients with the nephrotic syndrome requires a course of corticotropin early in the disease, followed by oral administration of cortisone three days per week, in a dose of 100 to 200 mg. per day for a period of six to eight weeks after diuresis. It is essential that prophylaxis against infection with antibiotics be offered during treatment with corticotropin. Penicillin should be given orally during treatment with cortisone.

There is no need for rigid limitation of intake of fluid in remissions and a general diet without "added salt" may be employed. Barnett expressed the belief that there should be as few hospitalizations in the course of the disease as possible, and that activity should be restricted as little as practicable. As regards the use of antibiotics, Barnett has advocated liberal use of these agents when threats of infection occur but he has cautioned against continual administration.

Brief mention should be made of two additional syndromes wherein renal failure is concerned, and their associated fluid and electrolyte problems. The first of these syndromes is lower nephron nephrosis. This condition may be the consequence of various insults to renal integrity such as transfusion with incompatible blood, infection and shock. Considerable damage to the renal tubule cells occurs and tubular and epithelial casts appear in the urine. Anuria follows during the period of regeneration of the tubule cells.

Administration of fluids must be held to the replacement of the daily estimated losses until renal function is resumed. A period of four to seven days usually is required for recovery.

A second condition is the low-salt syndrome which occurs as a result of an inadequate intake of sodium. Edema is apparent and renal function ceases. Prompt replacement therapy with hypertonic sodium chloride, in 2 per cent or 6 per cent solution, is effective in restoring renal function.

Summary

Only in anuric or oliguric states associated with renal disease should intravenous administration of fluids and salt be rigidly restricted. Fluids, when ingested orally, seldom produce aggravation of oliguric or anuric states. In chronic nephritis, if edema is absent, the intake of salt and water need not be restricted. Slight hope is offered for increased recovery rates among patients who present the nephrotic syndrome, through judicious use of corticotropin and cortisone. Additional help toward improvement of recovery rates can be expected from the antibiotics. Complete exclusion of salt from the diet alone can produce edema and oliguria. Treatment of the low-salt syndrome requires administration of hypertonic salt solutions.

CHEMOTHERAPY OF THE LEUKEMIAS AND LYMPHOMAS

J. M. STICKNEY, M.D.
Rochester, Minnesota

A FEW YEARS AGO a title such as this would have been meaningless because the treatment of leukemias and lymphomas was confined to roentgen therapy. Such treatment is still the standard by which any other must be measured, but at present several drugs have earned a place in everyday treatment and many others are under investigation.

Mustards and Related Compounds

Since World War I, the mustard gases have been known to depress lymphocytic tissue. As the result of investigation during World War II, the nitrogen mustards were selected for clinical trial in the treatment of neoplastic diseases. Methyl-*bis* (β-chloroethyl)-amine, referred to as HN_2, has proved least toxic and easiest to manage. It is clinically effective in Hodgkin's disease, lymphosarcoma and leukemia. HN_2 probably exerts its action by interfering with mitosis and is similar in action to roentgen therapy. HN_2 is soluble in water but disintegrates rapidly; therefore, it must be given immediately after being dissolved. Because HN_2 may produce thrombophlebitis with ease, it is wise to inject this material into the tube of an intravenous infusion set in which a 5 per cent solution of dextrose is being used. The dose per course consists of 0.3 to 0.5 mg. per kilogram of body weight, the average total dose being 25 to 40 mg.; it is given usually in two to four divided doses. The immediate reactions are nausea, vomiting, fever and headache. Sedation with barbiturates before and after the injection and the use of dimenhydrinate (dramamine) may help to modify these reactions. Depression of the neutrophils and platelets may occur in one to twenty-one days. Seldom is this severe enough to be troublesome, although blood transfusions and antibiotic therapy occasionally are necessary. A course of HN_2 may be repeated in four to six weeks.

This drug has been most effective in the treatment of Hodgkin's disease. Remissions such as occur after roentgen therapy are common, but on the average they are not maintained for so long a period. The best indication for treatment with HN_2 is widespread and systemic involvement. The more localized lesions of Hodgkin's disease are better treated with roentgen therapy unless viscera are involved. HN_2 has been effective when radiation has lost its effectiveness; at times, tissues that have become resistant to radiation appear to respond again after treatment with HN_2. The value of combined treatment has not yet been determined. Evidence exists to indicate that the results of treatment with HN_2 followed immediately by roentgen therapy, may be superior to the results of either agent used alone.

The mustards are somewhat less effective in the treatment of other lymphomas but what has been said about Hodgkin's disease applies to them. Although improvement may follow the treatment of chronic leukemia with HN_2, the drug has been used only occasionally in this disease. It is of no value in the treatment of acute leukemia.

A closely related compound is triethylene melamine (TEM—Lederle Laboratories Division, American Cyanamid Company). Its effect on neoplastic tissue appears to be identical to that of HN_2 but it can be given orally and is effective in smaller doses. The standard dose is 5 or 10 mg.; it is given in the morning before the patient has had anything to eat or drink. Nausea and vomiting may occur but are not common. Administration is not repeated until the effect of the preceding dose is ascertained. Daily determinations of leukocytes and platelets are essential because some patients, particularly those who have lymphatic leukemia and lymphosarcoma, are extremely sensitive to this drug. Patients who have Hodgkin's disease or chronic myelogenous leukemia tolerate larger doses. A maintenance dose of 5 mg. every seven to ten days is usually possible but careful adjustment of the dose is required in each patient. Severe depression of the bone marrow may occur rapidly and renal damage also may result.

Another group of compounds, the triethylenephosphoramides (TEPA—Lederle Laboratories Division, American Cyanamid Company) have similar properties and belong in the mustard

---

From the Section of Medicine, Mayo Clinic.

group. One of these, triethylene thiophosphoramide (thio TEPA), is fairly stable in solution and may be given orally in doses of 10 mg. It appears to have a wider margin of safety than does TEM. Its effectiveness has not been fully evaluated. It is of no value in the treatment of malignant melanoma.

Drugs of the mustard group have been used in the treatment of polycythemia vera, mycosis fungoides and metastatic carcinoma of the breast with variable but sometimes good results.

Antimetabolites

Another group of drugs that act in a different way has found a place in the management of leukemia. These agents are the antimetabolites, the best known of which are the folic-acid antagonists. Of many such compounds, 4-aminopteroyl glutamic acid (aminopterin) and amethopterin are now in general use and are available. Unlike most of the other drugs discussed in this paper, these agents are of value in the treatment of acute leukemia. These drugs are extremely toxic and easily produce signs that resemble acute deficiency of folic acid. Administration of citrovorum factor or folinic acid will counteract this reaction. Most workers agree that toxic effects and remissions in acute leukemia are closely related, so that these drugs must be given until the toxic state is at least closely approached. The type of leukemia that responds most often is acute or subacute lymphocytic leukopenic leukemia of childhood or adolescence. All types of acute leukemia, however, have responded and occasionally an adult will be helped.

Aminopterin is given in doses of 0.5 to 1.0 mg. and amethopterin in doses of 2.5 to 5.0 mg. daily. It is important to watch for signs of toxicity during administration of folic-acid antagonists. Alopecia is annoying but not serious. Stomatitis with shallow ulceration is often the first sign of toxicity and soon may be followed by severe abdominal pain accompanied by bloody diarrhea. The latter manifestations are caused by ulcerative enteritis, which is usually of grave prognostic significance. Severe depression of the bone marrow with neutropenia, leukopenia and thrombocytopenia may occur but often are also part of the natural course of the disease. Stomatitis or abdominal pain is an indication to discontinue administration of the drug or reduce the dose. As previously mentioned, folinic acid in doses of 1 to 3 mg. may be used to counteract the toxic effects. When any improvement is to occur, reticulocytosis and regeneration of erythrocytes in the bone marrow often precede the disappearance of leukemic cells. About 25 per cent of children who have acute leukemia undergo remissions after use of these folic-acid antagonists; the average remission lasts for three months. However aminopterin and amethopterin are difficult to handle, and in many instances an exceedingly sick patient is made even more uncomfortable.

Folic-acid antagonists may be used in the treatment of chronic leukemia and the lymphomas but the hazards do not justify such use because other methods are available.

Another drug that probably should be classified as an antimetabolite is also useful in the treatment of acute leukemia. It is 6-mercaptopurine (purinthol—Burroughs Wellcome & Co.), which apparently is an antagonist of hypoxanthine and adenine. It is given in a dose of 1 mg. per pound of body weight and is administered orally in tablets containing 50 mg. each. Although nausea and vomiting may occur after its use, stomatitis is rare. The incidence and duration of remissions produced by this drug are not yet fully known.

Hormones

Cortisone and corticotropin also have found a place in the treatment of acute leukemia. The doses used are large; 200 mg. of cortisone or 100 mg. of corticotropin is given as long as these agents are tolerated. Lymphocytic leukemias are most likely to respond and again most of the remissions occur in children. While use of these steroids induces good remissions in about 25 per cent of patients, the duration of the remissions averages about half of that obtained with the folic-acid antagonists, namely, six weeks instead of three months. One advantage of these hormones is their absence of severe toxic reactions. The folic-acid antagonists may be given simultaneously with the hormones or alternate courses of each agent may be used.

Cortisone also may be used in the treatment of Hodgkin's disease, in which it causes shrinkage of involved tissue but only short remissions. In chronic lymphocytic leukemia it may favorably affect the cutaneous lesions even though the numbers of blood cells are not altered. It also should be tried in hemolytic anemias secondary to lymphoma or chronic leukemia.

Miscellaneous Drugs

Urethan (ethyl carbamate) has been used in the management of chronic leukemia, particularly myelogenous leukemia. Administration of doses up to 3 gm. per day produces a decrease in the number of leukocytes and in the size of the spleen. The great difficulty with this drug is the nausea and vomiting which it may induce; however, restriction of doses to 1 or 2 gm. per day usually prevents this effect. My experience, however, has been that urethan is not so effective in inducing and maintaining remissions in chronic myelogenous leukemia as is roentgen therapy; it offers little benefit when the disease is radioresistant.

English workers recently have introduced a new compound, namely, 1,4-dimethanesulfonoxybutane (myleran—Burroughs Wellcome & Co.), which is reported to be effective in the treatment of chronic myelogenous leukemia. While my experience indicates that the drug may reduce the number of leukocytes, I cannot say whether it will prove more useful than urethan.

Many years ago, Fowler's solution was used in the treatment of leukemia, particularly in the chronic myelogenous type. Although this preparation is subject to the disadvantages of arsenical therapy, it is still a useful drug in this disease.

Comment

My colleagues and I have noted, as have others, that multiple remissions may occur in acute leukemia when the same drug is used on different occasions and that leukemia which becomes resistant to one drug may respond later to another. While such occasions are not common, they do occur. At all times, general supportive care, such as blood transfusion and antibiotic therapy, is carried out. While these factors may influence survival times, I do not think they are responsible for remissions. It must be emphasized that no curative agent for acute leukemia has been found and that remissions in children are not the rule and are rare in adults. At the present time I consider that the best program of treatment, if the patient or the parents understand the whole picture and still desire to have such treatment, is a trial of a folic-acid antagonist combined with or followed by use of corticotropin or cortisone. Administration of 6-mercaptopurine may be of value when the disease is resistant to use of folic-acid antagonists. It is questionable whether any drugs are useful in patients more than thirty years of age.

The availability of drugs that will augment or supplement roentgen therapy in Hodgkin's disease, the lymphomas and the chronic leukemias should be welcomed by the general practitioner, the pediatrician and the internist. It means that renewed interest may be taken in patients, formerly dismissed to the care of the radiologist and it should lead to closer co-operation between the family physician and the specialist. This should result in better care for the patient.

Summary

Roentgen therapy remains the standard treatment for Hodgkin's disease, lymphoma and chronic leukemia.

Nitrogen mustard is effective in the treatment of these diseases, particularly Hodgkin's disease. Related compounds that may be given orally are triethylene melamine and triethylene thiophosphoramide. In selected cases they are useful agents.

The folic-acid antagonists, as well as corticotropin, cortisone and 6-mercaptopurine cause remissions in acute leukemia in children, and young adults but such remissions are not long maintained.

SCHOLARSHIPS IN PUBLIC HEALTH

The Harvard School of Public Health is initiating postgraduate scholarships in amounts ranging up to $5,000 to qualified candidates desiring to study at the school during the academic year 1954-1955. These scholarships are available to (1) physicians, dentists, and veterinarians interested in preventive medicine and seeking training in one or more public health specialties leading to a master of public health or a doctor of public health degree; (2) industrial physicians seeking training in industrial medicine leading to a master of industrial health degree; (3) public health nurses with a college degree and satisfactory field experience who wish additional public health training leading to a master of public health degree; (4) public health engineers seeking additional training and research experience in one or more public health specialties leading to either a master of science in hygiene or a doctor of science in hygiene degree; and (5) college graduates with academic experience in the natural sciences who desire training and research experience in one of the sciences related to public health and leading to either a master of science in hygiene or a doctor of science in hygiene degree. Applications must be filed by April 30. Winners will be announced June 1. Information may be obtained from the Secretary, Harvard School of Public Health, 55 Shattuck St., Boston 15.

Laboratory Aids to Medical Practice

Sponsored by
The Minnesota Society of Clinical Pathologists

OFFICE HEMATOLOGY

JAMES L. JAECK, M.D.
La Crosse, Wisconsin

"OFFICE HEMATOLOGY" refers here to routine blood tests performed on outpatients *in the doctor's office.* Few physicians can obtain or maintain a registered medical technologist. Many rely on the "office nurse," who may be neither nurse nor technician. The doctor himself, therefore, is responsible for the reliability of his office laboratory. Unreliable laboratory data are worse than none at all!

Office hematology should provide adequate screening for primary hematologic disease and should furnish dependable quantitative information for clinical evaluation and treatment of secondary hematologic problems. Realize the limitations of the office laboratory and freely seek hematologic consultation. Do not be guilty of the diagnosis of anemia by therapeutic trial. Have respect for persistent leukopenia with anemia. Use caution in diagnosis and prognosis of adenopathy with lymphocytosis in children and young adults; in such cases, send blood for determination of heterophil antibodies once a week for three weeks and send good blood smears to a clinical laboratory.

Choose office blood tests for maximal dependable information, rapidity and minimal cost but never trade time for accuracy. A single determination has much less significance than a series, which may show a "trend." Repeat tests whose results are inconsistent with clinical impressions. No one hematologic finding is pathognomonic. A minimal hematologic screening for every new office patient should consist of: (1) hemoglobin or hematocrit; (2) total leukocyte count and (3) peripheral blood smear. An erythrocyte count gives little information and has great personal and technical error; it may well be omitted unless cell indices are to be done. The erythrocyte count may be normal in hypochromic anemia. The hematocrit is more valuable than either hemoglobin or erythrocytes in following the treatment of anemia.

I would do a differential count only when indicated by the number of leukocytes or the appearance of the blood smear. The differential count requires a well-stained smear and proper training in morphologic hematology or it is worthless. I often receive blood smears for diagnosis accompanied by total and differential leukocyte counts, yet find the smear so poor that I cannot identify cells for a differential count, to say nothing of returning a morphologic diagnosis.

Depending on the size of the office laboratory and on trained personnel, one could set up certain unit or group tests to be done on the basis of clinical diagnosis and results of basic screening tests. For the study of anemias, such a unit might include: (1) complete blood counts; (2) hematocrit; (3) cell indices and (4) reticulocyte count. For a study of hemorrhagic tendencies the unit also would include: (1) bleeding time; (2) clotting time; (3) clot retraction; (4) platelet count and (5) prothrombin time.

Hemoglobinometry

Determination of hemoglobin is the most commonly used of all office blood tests, but it also has the greatest range of error (5 to 40 per cent). Error is referable to: (1) differences in methods and large inherent error; (2) lack of uniform standard of reference; (3) pipette and instrument error; (4) personal technical errors in visual colorimetric methods and (5) instability of color of hemoglobin and acid hematin.

The Tallqvist scale and Dare method have the

This is the fourteenth in a series of editorial reports sponsored by the Minnesota Society of Clinical Pathologists and designed to foster closer relationships between clinicians and pathologists.

Dr. Jaeck is Pathologist and Director of Laboratories, Gundersen Clinic and Lutheran Hospital, La Crosse, Wisconsin.

greatest inherent error. The popular Sahli method with careful technique and calibrated pipettes and tubes can attain a satisfactory accuracy of ±5 per cent. The following precautions reduce technical error in the Sahli method: (1) use a *dry*, bubble-free pipette; (2) use clean diluting fluid; (3) wipe off blood on outside of pipette; (4) fill pipette accurately (if overdilution occurs, discard and start over); (5) discard first drop of diluting fluid; (6) rinse acid in Sahli tube back and forth several times; (7) stir constantly while delivering pipette sample into Sahli tube; (8) allow a minimum of twenty minutes at room temperature before diluting the acid hematin to match color standard; (9) stir while diluting and match color in same good light each time; (10) read meniscus in Sahli tube in grams per 100 cc. of blood and (11) use tubes made by same manufacturer as standard.

The Haden-Hausser hemoglobinometer (larger laboratory model) has the advantage of allowing use of the blood sample in the white pipette. It also allows approach of the end point from either side without the danger of passing it. Both Sahli and Haden-Hausser techniques are visual colorimetric acid-hematin methods subject to inherent errors of fading and the use of artificial permanent color standards. Each physician must determine, for the instrument used, the equivalent in grams per 100 cc. for 100 per cent hemoglobin on a series of healthy, normal adults with erythrocyte counts near 5,000,000. A value of 15 gm. per 100 cc. of blood is the average acceptable standard for this region.

Hematocrit

The volume per cent of packed erythrocytes is the most accurate index of circulating hemoglobin and erythrocytes. The hematocrit is quantitative, simple, informative and does not require unusual technical skill. A good method is that of Wintrobe, as detailed in Wintrobe's *Clinical Hematology*. The equipment required includes Wintrobe hematocrit tubes, capillary pipettes and any standard centrifuge capable of 2,500 to 3,500 rpm. Some precautions for accurate results include: (1) dry anticoagulant in clean tubes; (2) invert blood sample in oxalate tube ten to twelve times; (3) fill hematocrit tube immediately after mixing; (4) let blood settle in hematocrit tube for one hour before centrifuging (this gives sharper demarcation of layers and also permits a sedimentation rate reading in the tube); (5) centrifuge for thirty minutes and (6) use hand lens to read level of packed erythrocytes.

The normal hematocrit value in men is 47 ± 7 per cent and in women is 42 ± 5 per cent. In anemia, the value may go as low as 8 per cent, whereas in polycythemia it may be as high as 80 per cent.

Blood Cell Counts

A likely source of error in cell counts is wet pipettes. A dry pipette is one in which the bead is free in the bulb. The best way to assure a dry pipette for each count is to have enough on hand for the entire day's use without employing any pipette twice. A clean dry counting chamber is also imperative. Discard pipettes with even a tiny chip at the tip. We have greatly reduced technical errors in dilution by replacing all conventional red and white pipettes with Tri-Lyne pipettes. Bard-Parker pipettes probably are the best of the conventional types because they are calibrated individually and marked with a correction factor. The counting chamber must not be overfilled or underfilled for an accurate count.

Blood Smears

These are the most important and also the poorest done of all office hematology procedures. Any smear might be the one you want to send to a pathologist or hematologist. With a little personal supervision, Wright-stained blood smears done in the office can be just as good as those done in the clinical laboratory.

Clean slides are essential. Slides in a freshly opened box are not clean. Wash up a batch in ordinary soap and water. Rinse in plenty of hot clean water, with a final rinse in distilled water. Store in 95 per cent alcohol (ethyl) until ready for use. The best smears use a small drop of blood (pinhead size) spread lightly, evenly and without a final push or lift. Dry smear rapidly in air; do not blow or use a fan. High humidity in summer makes poor smears and poor stain affinity. I know of no remedy. Use only certified Wright stain (prepared or powder). If you make your own, use only acetone-free methyl alcohol. Keep stock Wright stain in tightly stoppered bottle. Dispense it with a small dropper bottle. Filter stain each day. Keep bottle of stain away from strong acids or alkalies.

(Continued on Page 292)

President's Letter

WE MEET AGAIN

The tradition of fine medical meetings will be carried on again in 1954. The annual meeting of the Minnesota State Medical Association is scheduled for Duluth on June 7, 8, and 9, and from all indications, the convention promises to be outstanding in all respects.

The scientific program will be one of unusual value to the medical profession of this area, specialist and general practitioner alike. Subjects run the gamut of medical interests, including such worthy subjects as ulcerative colitis, a symposium on fractures, a symposium on cortisone and ACTH, treatment and diagnosis of hypertension, diagnosis of pulmonary diseases, a symposium on anesthesiology, hydronephrosis, treatment of blood dyscrasias, anemias in pregnancy, plasma expanders, and a section on what's new in medicine, surgery, radiology, pediatrics, obstetrics and gynecology.

The usual wide selections in subject matter will again be found in the round-table discussion luncheons. Many guest speakers from the general session will lead these discussions, giving expert advice and opinion to the physicians who look on the annual meeting as an excellent opportunity to gain additional information as an adjunct to their everyday practices.

Assurance of excellent hotel accommodations has been given by the Duluth Chamber of Commerce.

Business sessions scheduled during the meeting include the following. The Council meets daily, beginning on Saturday, June 5. The House of Delegates will begin its sessions on Sunday, June 6. Association committees will meet on Tuesday and Wednesday, June 8 and 9.

A new feature this year will be one or two "consultation" booths, to be found on the convention floor at the Duluth Armory. Plans include one booth on general fracture subjects, another on obstetrics and gynecology. Here, the physician can bring his own special problems, outline them to experts in the field, and discuss their implications and treatment.

Many important social events have been planned. Special organizations will be meeting simultaneously with the State Association, holding special luncheons and dinners for their members.

Recreation has been arranged by the Committee on Local Arrangements. Golf, lake fishing and skeet and trap shooting will give the busy doctor a fine chance for relaxation away from the heavy schedule of scientific and business sessions. Duluth offers many good accommodations for such affairs, and physicians are urged to take time out to enjoy them.

There are many things one might mention in giving a general outline of the meeting of the year. With all the various events scheduled, it is a matter of choice on what to concentrate. But there is one important thing to remember: your attendance at the meeting in Duluth will be well worth the few days away from your practice. It offers postgraduate education from experts in all fields; it offers meetings with your special interest group; it offers time for relaxation with your colleagues throughout the profession; and it offers opportunity to meet and discuss Association problems and policy which are common to the nation's entire medical profession.

For interesting and informative medical sessions, your meeting calendar should be marked for the Minnesota State Medical Association annual convention, Duluth, Minnesota, June 7, 8 and 9, 1954.

President, Minnesota State Medical Association

Editorial

Arthur H. Wells, M.D., *Editor;* Henry G. Moehring, M.D., and John F. Briggs, M.D.

CANCER DETECTION COST vs. VALUE OF LIFE

AFTER almost twenty years of experience with Cancer Detection Centers, the medical profession should soon be able to properly evaluate many of the practical aspects of these periodic examinations of apparently healthy individuals. Perhaps the closing of large numbers of the Centers throughout the country and the recent shift of emphasis by the American College of Surgeons to Cancer Diagnostic Clinics (patients come with complaints) are signs of practicality.

Three principal questions have confronted the profession. (1) Which of the individual tests performed in the examinations is worth its salt in terms of lives saved per dollar spent? (2) Is the specialty clinic approach to cancer detection more economical than the "Every Doctor's Office a Cancer Detection Center" plan? (3) What new tests for cancer detection are there to be discovered? The answer to the last question could make almost any amount of money expended in this type of research worthwhile.

There is some value in nearly all of the clinical and laboratory procedures generally performed in these examinations. The question is, are they economically sound? An x-ray examination of the chests of more than a million people in the Los Angeles area was worth the cost in numbers of cases of tuberculosis discovered, isolated and treated. On the other hand, if the study had been carried out solely for the purpose of discovering bronchogenic cancer, rough calculation leads one to the conclusion that it would cost approximately $100,000 per life saved from this disease. As a matter of fact, there is some question as to the economy of any type of roentgen study conducted solely for the detection of cancer in the symptomless and signless individual.

From the figures of 11,000 examinations for cancer presented by Hitchcock and Aust elsewhere in this issue, one can see that only ten possible curable, asymptomatic cancers were found which were not easily accessable to the examining fingers and eyes of a physician in general practice. The salvage from these ten cases of deep-seated cancer may have been five lives. Had the ten eventually developed symptoms and gone to their family physicians in the conventional manner, at least two would have been saved. Would the difference of three lives cost an additional $50,000? We are badly in need of a dollars and cents approach to this subject concurrent with the scientific study.

Physicians are on solid economic ground when the cancer detection (in the apparently healthy person over forty years) is limited to a study of cancer symptomatology and a careful physical examination including cervical and rectal visualization. Any clues of "internal" cancer picked up in the clinical history must receive the proper diagnostic attention. The corrected cost of this type of cancer detection will be between $1,000 and $2,000 per life saved from cancer. In addition, there will be a bountiful disclosure of "precancerous" and non-neoplastic diseases. The "Every Doctor's Office . . ." program of your Committee on Cancer deserves the whole-hearted support of the profession.

BLUE SHIELD'S PLAN B

CONCLUDING that open, written debate on important issues serves the profession best, your Board of Editors publishes the following editorials on the Pro and Con of Plan B of Blue Shield for your careful consideration.

PRO

Both Blue Shield and Blue Cross were organized to provide people with a means of paying their medical-care and hospital bills at a cost within their financial reach. During the depression of 1932, many people throughout the United States were unable to pay their hospital bills, as a result of which the occupancy of hospitals dropped to a hazardously low level. To remedy this situation, Blue Cross devised a plan whereby it accepted small monthly payments from those who joined the movement for the payment of their hospital bills. It was a non-profit, prepayment plan to provide hospital care at a cost which people could afford.

Similarly, the depression of 1937 created serious problems in the payment of medical care bills.

Many people were unable to pay their doctor bills, and both the medical profession and the government became interested in what was referred to as "the high cost of medical care." The government's solution appeared in the form of the first Wagner-Murray-Dingell bill introduced in Congress in 1939. The medical profession's answer appeared the same year in the organization of the first Blue Shield medical-care plan fashioned after the Blue Cross hospital plan.

In this problem of the so-called "high cost of medical care," classification of people according to their incomes and their ability to pay for medical care has been necessary. Indigent persons receive their medical care at the cost of some unit of government, local, state or federal, and, consequently, are not concerned in pre-payment plans. The wealthy are able to pay the costs of their medical care, and do not constitute part of the problem. This leaves those in the low and modest income brackets as the ones who must be provided medical care at a cost they can afford. If medicine, through Blue Shield or some other equally effective means, does not furnish the answer of providing medical care for those with low or modest incomes, the solution might be forthcoming from government, labor or industry. Thus, Plan B has the rôle of furnishing part of the answer by offering medical care to those with modest incomes within the reach of their pocketbooks.

As a first step in the development of Blue Shield's, Plan B, the issuance of a contract with service benefits for families with annual incomes less than $5,000 was first discussed with the Council and the Houe of Delegates of the Minnesota State Medical Association at the Radisson Hotel in May, 1952. No action was asked nor taken regarding it, but neither were any adverse comments made regarding it. The matter was again presented to the Council at the meeting of the Minnesota State Medical Association in May of 1953. At this time, the contract's increase of fees to approximately 50 per cent more than those of the standard contract, and the contract's income limits for service benefits of $3,600 for single persons and $5,000 for families were fully presented. No objections were raised at the Council meeting, and the matter was referred to the House of Delegates. Here again, these same two features of Plan B were clearly discussed before the House of Delegates, which then approved the plan with only one dissenting vote. Plan B, then, was developed only after it was approved by the governing body of organized medicine in Minnesota.

After the announcement of its issuance, two objections to Plan B were voiced by some members of the medical profession. The first of these concerns fees. As a first step in the deteremination of an adequate fee schedule, a questionnaire was sent to the component medical societies asking them to list the fees customarily charged by their members for some of the more common medical-surgical-obstetrical services. Replies were received from nineteen of the thirty-two component medical societies. Then, four of the highest Blue Shield fee schedules of such higher income contracts as Plan B were assembled. The fees selected for the Plan B schedule consisted principally of the highest or next highest fees of the four Blue Shield schedules. By comparison with the fees listed in the questionnaires, the Plan B fees were usually above those customarily charged by members of the various component societies. The final Plan B fee schedule has fees, in general, 50 to 55 per cent higher than those of Plan A. Also, the Plan B fee schedule ranks among the highest Blue Shield fee schedules in the United States.

Despite its generally favorable comparison with other fee schedules, it has been pointed out that it still contains some inequities. To overcome these objections, the Board of Directors has appointed a special committee whose purpose it is to meet with the authorized representatives of any group of physicians for the review and adjustment of inequities. Efforts are now being made to adjust inequities of fees and other Plan B matters in this manner.

The second objection to Plan B is that Plan B might establish the fees for 75 per cent of the population. This statement is based upon the fact that an average of approximately 75 per cent of single persons and families in Minnesota have incomes less than the service income limits of the Plan B contract.

Enrollment under Plan B contracts in other states, as well as Plan A enrollment here in Minnesota, fails to support such a statement. In one of the states having such a contract, after several years of comparatively successful Plan B enrollment, only a relatively small percentage of the population had Plan B coverage. Were this same rate enrollment of Plan B to occur in

Minnesota, is it likely that Plan B might establish fees for 75 per cent of the population?

It has been calculated from income data available in 1949 that an average of approximately 70 per cent of single persons and families then had incomes less than the standard contract's service income limits. This is only five per cent less than the percentage now said to be potentially eligible for service benefits under Plan B, yet no statements have been made that the standard contract established the fees for 70 per cent of the population.

Other economic factors have an important bearing on these service income limits. For instance, since Blue Shield was organized there have been five general, national wage and salary increases. These salary raises have elevated the incomes of many workers to the point where they are no longer eligible for Plan A service benefits. One of the Building and Construction Trades Council in Minnesota lists twenty-nine types of construction workers whose lowest hourly wages make them ineligible for Plan A service benefits. The Agriculture Department and the Farm Management Office of the University Extension Service found the average annual farm labor income in the southern half of Minnesota in 1952 to be $3,950. Are not these wage earners and farmers the types and groups of people who were originally intended to have service benefits under the Blue Shield program?

Inflation also has developed to the point where the dollar today has only 60 per cent of its value in 1938. This means that a family with an annual income of $5,000 today has the same purchasing power as a family with a $3,000 annual income sixteen years ago. Families of three or four persons, and usually families in this income bracket are larger, are often unable to pay for medical and hospital care. Here again, it is apparent that these are the same people for whom Blue Shield's service benefits were originally planned.

Thus, Plan B is a necessary part of the answer to the problem. As a complement of Plan A, and with a catastrophic illness rider, Plan B provides the answer to the broad problem often referred to as the high cost of medical care. Plan A alone will not solve the problem. Plan B is an essential part of the program of providing medical care for people with low or modest incomes at costs they can afford. Recommendations have emanated from high authorities in both the past Democratic and the present Republican administrations that voluntary prepaid medical care plans provide greater benefits for more people. And, if this challenge is not met by the medical profession through such a medium as Minnesota Blue Shield's Plan B, there is little doubt that the answer may be forthcoming from some other source.

E. J. Simons, M.D.

CON

Blue Shield of Minnesota has rightfully claimed the support of the preponderant majority of physicians in Minnesota since its inception in 1947. Members of the State Medical Association have recommended this form of voluntary pre-paid medical insurance as the best buy in its field. The medical profession has supported the Blue Shield as its own medical insurance plan believing that it would materially relieve the financial burden of sickness upon Minnesota families.

The Blue Shield contract has proved its value in the succeeding years. It has earned the support of the public and the profession generally. Although in many instances the fees paid were inadequate, the physician dealing with a patient in reasonably good financial circumstances could ask for supplemental payment. Participating physicians were required to accept the Blue Shield payment as full settlement of medical charges for indigent and low income groups: single individuals with an income less than $2,000.00 per year or families with less than $3,000.00. Minnesota physicians participating in this plan subscribed to these limitations and restrictions. The profession accepted the inevitable inequities that occur when a third party sets the fee, occasionally providing medical care without fee in some cases which required the services of more than one physician. The percentage of cases falling into such a category was small.

This happy state of affairs has been severely disturbed by a letter sent out December 23, 1953, by Minnesota Medical Service Incorporated (Blue Shield), outlining a new plan, the Plan B contract, to be available to the public after March 1, 1954. Quoting from this letter:

> "Service benefits under this Plan B contract will be available to single persons with annual incomes less than $3,600.00 and to family participant subscribers whose annual family income is less than $5,000.00 The Blue Shield allowances for eligible services provided the subscribers whose incomes are below the level stated for each type of subscribers—single or family—*will consti-*

tute payment in full. If the annual income is above these levels the subscriber is responsible for the balance of the doctor's usual fee."

This means that the Blue Shield allowance represents payment in full to the participating physician for the medical obligations of family subscribers with annual incomes not in excess of $5,000.00 per year and single subscribers having annual incomes not in excess of $3,600.00 per year. It is estimated that approximately 75 per cent of the gainfully employed people of the State of Minnesota have annual earnings within these income levels. It is reasonable to assume therefore that this plan, if it finds wide public acceptance, will in effect establish fees for 75 per cent of the population of this state.

Large segments of Minnesota physicians are alarmed by the introduction of this drastic change in Blue Shield coverage. The so-called full coverage under the proposed plan means absolute regulation of physicians' fees not only for its indigent and low income groups but also for the average man and necessarily for the above average as well! Inequities that were of little consequence affecting a small indigent group can no longer be ignored. In particular, the nonoperating specialties, internal medicine, dermatology, neuropsychiatry, pediatrics, and anesthesiology will suffer. However variously the new plan may create economic burdens, groups within the entire profession must suffer equally the loss of independence. Several groups have already voiced their opposition to the plan. Both the Minneapolis and Saint Paul Societies of Internal Medicine have had special meetings expressing their opposition. When the proposed plan was presented by officers of the Blue Shield recently before a special meeting of the Minneapolis Asbury Hospital Staff, every comment was critical.

It is evident that large sections of the membership of the Minnesota State Medical Association, probably the majority, are opposed to extension of the complete fee service to a $3,600.00 and $5,000.00 level.

It seems proper, therefore, to suggest to the Board of Directors that this is not an opportune time to inaugurate this new plan. It might be further suggested to them that they more carefully take soundings of medical opinion before making drastic changes in the Blue Shield contracts.

R. Berman, M.D.

THE ANNUAL MSMA MEETING

The annual meeting of the Minnesota State Medical Association to be held June 7, 8, and 9 in Duluth shows every promise of being a successful one by everyone's standards. You can help make it successful by sending in your reservations for housing, for specialty meetings, and for special events *early*.

The hotel managers have given assurance that housing for the meeting will be even better than in 1950. You are urged to minimize any causes of discontent by:

1. Mailing or telephoning in your reservations early.
2. Stating your preference, and an alternate or two, of type of accommodations.
3. Stating your checking out time, if possible.

Since reservations will be held until 4:00 P.M., it is suggested that you send a deposit with your reservation request, if you think you will sign in *after* 4:00 P.M. (Deposit will be returned, if the reservation is cancelled before 4:00 P.M.)

Minnesota State Medical Association

101st Annual Meeting

Duluth, Minnesota
June 7, 8 and 9, 1954

Preliminary Program

BUSINESS SESSIONS

SATURDAY, JUNE 5
Hotel Duluth

2:00 P.M.—Council.................... English Room
6:00 P.M.—Council.................... English Room

SUNDAY, JUNE 6
Hotel Duluth

8:30 A.M.—Council.................... English Room
10:00 A.M.—Reference Committees................ Rooms to be assigned
1:30 P.M.—House of Delegates.............. Ballroom
8:00 P.M.—House of Delegates.............. Ballroom

MONDAY, JUNE 7
Hotel Duluth

8:30 A.M.—Council.................... English Room
12:15 P.M.—House of Delegates............. Ballroom

TUESDAY, JUNE 8
Hotel Duluth

8:30 A.M.—Council.................... English Room
8:30 A.M.—Committees......................... Rooms to be assigned

WEDNESDAY, JUNE 9
Hotel Duluth

8:30 A.M.—Council.................... English Room
8:30 A.M.—Committees......................... Rooms to be assigned

SOCIAL EVENTS

SUNDAY, JUNE 6

Buffet Supper

American Medical Women's Association, Inc., Minnesota Chapter

6:30 p.m., Home of Elizabeth Bagley, M.D., 2524 Branch Street
Open to all visiting women doctors. Dr. Marie Bepko will show colored slides from the Fourth Congress of the Pan-American Medical Women's meeting in New York City.

MONDAY, JUNE 7
Luncheons

Minnesota Chapter, American College of Chest Physicians
12:15 p.m.

Minnesota Medical Foundation
12:15 p.m.
Speaker: Clarence Dennis, M.D., New York

Dinners

Minnesota Academy of General Practice

6:00 p.m., Ballroom, Hotel Spalding

Open House, Minnesota State Medical Association
9:00 p.m., Ballroom, Hotel Duluth

Minnesota Radiological Society
6:00 p.m., Social Hour
7:00 p.m., Dinner
Speaker: Philip J. Hodes, M.D., Philadelphia—"An Evaluation of Body Section Radiography"
Northland Country Club, 39th Avenue East and Superior Street. Tickets, $5.00. Reservations should be made with Dr. John R. McNutt, 824 Medical Arts Building, Duluth.

TUESDAY, JUNE 8
Dinners

Minnesota Society of Clinical Pathologists
6:00 p.m., Annual Dinner and Business Meeting—House of Dr. A. H. Wells

Annual Banquet, Minnesota State Medical Association
7:00 p.m., Ballroom, Hotel Duluth

12:15 ROUND TABLES

Duluth and Spalding Hotels

MONDAY, JUNE 7

Anesthesia as a Maternal Mortality Factor
Frederick J. Hofmeister, Milwaukee, Wisconsin

TUESDAY, JUNE 8

Use of Tracheotomy in Chest Injuries
W. P. Eder, Minneapolis
Treatment of Burns in Children
Tague C. Chisholm, Minneapolis
Emergency Treatment of Nerve Injuries
Robert L. Merrick, Saint Paul
Indications and Contraindications for the Use of the Hormones (ACTH and Cortisone) in Gastrointestinal Disorders
J. Arnold Bargen, Rochester

Skin Manifestations in Systemic Disease
John F. Schmid, Duluth

Acute Urinary Obstruction in the Male
Otto C. Phares, Saint Cloud

Drugs in Peptic Ulcer
E. E. Gambill, Rochester

The Injured Hand
J. C. Feuling, Duluth

WEDNESDAY, JUNE 9

Diagnostic Difficulties in Carcinomas of the Lungs
F. F. Callahan, Saint Paul

Evaluation of Operations for Peptic Ulcer
C. W. Lillehei, University of Minnesota

Relation of Blood Volume to Gastrointestinal Hemorrhage
J. E. Twomey, Minneapolis

Practical Application of Cytologic Technique for Malignancy
A. H. Wells, Duluth

Anesthesia in Tonsillectomy
F. C. Jacobson, Duluth

Functional Uterine Bleeding
R. F. Sturley, Saint Paul

Treatment of Plantar Warts
R. W. Goltz, Minneapolis

Diagnosis and Treatment of Blood Dyscrasias
Paul S. Hagen, Saint Paul

GENERAL SESSION

Duluth Armory

MONDAY, JUNE 7

A.M.

8:30 Visit Scientific and Technical Exhibits.... Armory

9:00 TREATMENT OF HYPERTENSION
Moderator—R. M. Shick, Rochester
Henry A. Schroeder, Saint Louis, Missouri
A. C. Corcoran, Cleveland, Ohio
Robert W. Hollenhorst, Rochester
Question and Answer Period

Intermission

10:15 Visit Scientific and Technical Exhibits.... Armory

11:00 Plastic Operations for Hydronephrosis
Frederic E. B. Foley, Saint Paul
Comments
Ormond S. Culp, Rochester

11:40 Staphylococcal Sepsis; Control with Antibiotics
Robert I. Wise, Assistant Professor, Department of Medicine, University of Minnesota

P.M.

12:15 Miscellaneous Luncheons
Round-Table Luncheon

1:30 Visit Scientific and Technical Exhibits..Armory

2:00 (To be announced)

2:30 RUSSELL D. CARMAN MEMORIAL LECTURE
Pitfalls in the Diagnosis of Pulmonary Diseases
Philip J. Hodes, Professor of Radiology, School of Medicine, University of Pennsylvania, Philadelphia

Intermission

3:15 Visit Scientific and Technical Exhibits..Armory

4:00 SYMPOSIUM ON ANESTHESIOLOGY
Moderator—Ralph T. Knight, Minneapolis

Hypotension During Surgery and the Immediate Postoperative Period
Ferdinand C. Jacobson, Duluth

Cardiac Arrest During Anesthesia
James H. Matthews, Minneapolis

Will Analgesia Evolve from a Century of Anesthesia?
John S. Lundy, Rochester

Trichlorethylene—Its Possibilities for the General Practitioner
O. Sidney Orth, Professor of Pharmacology, University of Wisconsin, Madison

5:00 Visit Scientific and Technical Exhibits..Armory

6:00 Special Dinners

9:00 Open House....................Hotel Duluth

GENERAL SESSION

Duluth Armory

TUESDAY, JUNE 8

A.M.

8:30 Visit Scientific and Technical Exhibits..Armory

9:00 SYMPOSIUM ON PROBLEMS ARISING IN THE CLINICAL USE OF CORTISONE, HYDROCORTISONE AND CORTICOTROPIN

Problems Arising in the Treatment of Adrenal Insufficiency
Edmund B. Flink, Minneapolis, Moderator

Untoward Effects Upon the Gastrointestinal Tract
Eric E. Wollaeger, Rochester

The Use, Abuse and Limitations of Steroid Therapy in Dermatology
Francis W. Lynch, Saint Paul

Problems of Dosage in Treatment of Rheumatoid Arthritis
L. Emmerson Ward, Rochester

Problems Arising From Suppression of Adrenal Cortical Function by Cortisone and Hydrocortisone
Robert M. Salassa, Rochester

Pathology of the Pituitary and Adrenals
Warren A. Bennett, Rochester

Question and Answer Period

Intermission

10:15 Visit Scientific and Technical Exhibits..Armory

11:00 The Clinical Management of Fulminant Infections in Childhood
Edward B. Shaw, Clinical Professor of Pediatrics, University of California Medical School, San Francisco

11:30 ARTHUR H. SANFORD LECTURESHIP IN PATHOLOGY
John R. Schenken, Professor of Pathology, University of Nebraska Medical School, Omaha

P.M.

12:15 Miscellaneous Luncheons
Round-Table Luncheons

1:30 Visit Scientific and Technical Exhibits..Armory

2:00 ULCERATIVE COLITIS

Medical Aspects
J. Arnold Bargen, Rochester

Psychiatric Aspects
L. R. Gowan, Duluth

Surgical Aspects
Clarence Dennis, New York

Question and Answer Period

Intermission

3:15 Visit Scientific and Technical Exhibits..Armory

4:00 SYMPOSIUM ON FRACTURES OF THE SPINE AND LOWER EXTREMITIES

Fractures of the Spine and Pelvis
John C. Ivins, Rochester

Fractures About the Knee Joint
Harry B. Hall, Minneapolis

Fractures of the Tibia and Fibula in Adults
Malvin J. Nydahl, Minneapolis

Fractures of the Lower Extremity in Children
S. S. Houkom, Duluth

5:00 Visit Scientific and Technical Exhibits..Armory

7:00 Annual Banquet......Ballroom, Hotel Duluth

GENERAL SESSION

Duluth Armory

WEDNESDAY, JUNE 9

A.M.

8:30 Visit Scientific and Technical Exhibits..Armory

9:00 Diagnosis and Treatment of Hemolytic Anemia
Paul S. Hagen, Saint Paul

Anemias in Pregnancy
Roy G. Holly, University of Minnesota

Plasma Expanders
A. R. Curreri, Associate Professor of Surgery, University of Wisconsin Medical School, Madison

Question and Answer Period

Intermission

10:15 Visit Scientific and Technical Exhibits..Armory

11:00 Minnesota Division, American Cancer Society

P.M.

12:15 Round-Table Luncheons

1:30 Visit Scientific and Technical Exhibits..Armory

2:00 WHAT'S NEW?

Moderator—F. J. Hirschboeck, Duluth

In Medicine
C. J. Watson, Professor and Head, Department of Medicine, Medical School, University of Minnesota

In Surgery
Owen H. Wangensteen, Professor of Surgery and Chairman, Department of Surgery, Medical School, University of Minnesota

In Radiology
Leo G. Rigler, Professor and Head, Department of Radiology, Medical School, University of Minnesota

In Pediatrics
Irvine McQuarrie, Professor and Head, Department of Pediatrics, Medical School, University of Minnesota

In Obstetrics and Gynecology
John L. McKelvey, Head, Department of Obstetrics and Gynecology, Medical School, University of Minnesota

Question and Answer Period

SPECIAL SESSIONS

MONDAY, JUNE 7

A.M.

10:00 Minnesota Academy of Ophthalmology and Otolaryngology, St. Luke's Hospital Auditorium

Hearing Loss in Children—Detection, Treatment and Rehabilitation....................
Kinsey M. Simonton, Rochester

Chronic Middle Ear Suppuration—Today......
L. R. Boies, Minneapolis

Retrolental Fibroplasia.......................
Erling Hansen, Minneapolis

Some Types of Retinal Vascular Occlusions....
Henry P. Wagener, Rochester

P.M.

1:00 Round Table Luncheon
Discussion on Vertigo.......................
Terrance Cawthorne, London, England

TUESDAY, JUNE 8

A.M.

9:00 Minnesota Society of Clinical Pathologists
Tumor Seminar..............St. Mary's Hospital

Moderator—Benjamin Castleman, Professor of Pathology, Harvard Medical School, Boston, Massachusetts

11:30 Arthur H. Sanford Lectureship in Pathology..
Duluth Armory

P.M.

12:00 Luncheon....................St. Mary's Hospital

2:00 Tumor Seminar (Continued)..................
St. Mary's Hospital

6:00 Annual Dinner and Business Meeting

Plan to attend the

annual meeting

at Duluth

You will learn much

that is new and

of interest

The Dean's Page

THE DEPARTMENT OF MEDICINE

From time to time on this page, we want to bring you information concerning the teaching and research activities of the various departments and divisions of the Medical School. The Department of Medicine is one of the larger departments and carries an extemely important responsibility for teaching. It is composed of three divisions: Internal Medicine, Dermatology, and Clinical Laboratory Medicine. These divisions are directed, respectively, by Doctors Cecil J. Watson, Henry E. Michelson, and Gerald T. Evans. Dr. Evans is also in charge of the Laboratory Service of the Hospital. The Division of Clinical Laboratory Medicine is responsible for teaching clinical chemistry and microscopy to the sophomore medical students and for teaching the application of laboratory methods to clinical medicine during the junior year.

In addition to the course in clinical chemistry and microscopy, the department is responsible for the following teaching:

1. *Physical Diagnosis,* given in the winter quarter of the sophomore year. Because this course constitutes the student's first contact with patients, it is of particular importance. Students study physical signs at the bedside at the University Hospital and either at the Veterans Hospital, the Minneapolis General, or the Ancker Hospital in St. Paul.

2. *Introduction to Clinical Medicine.* This is a "didactic" course which meets for two hours weekly during the first two quarters and one hour weekly during the third quarter of the Junior year. Students are provided with a lecture syllabus (*The Outlines of Internal Medicine*) which covers the basic material and, for the most part, the class hours are devoted to clinics and demonstrations and discussion of new advances.

3. *The In-Patient Clinical Clerkship* in the Junior year. Students are assigned for ten weeks to the Department of Medicine. Each student spends half of this time at the University Hospital studying patients under close supervision on the wards. Their detailed histories and physical examinations are incorporated into the charts. A student at the University Hospital is responsible also for a considerable amount of the laboratory work. This is carefully supervised. Each student devotes the other half of his medical clerkship to similar clinical work either at the Minneapolis General Hospital or the Veterans Hospital.

4. *The Out-Patient Medical Clerkship* in the Senior year. The student is assigned a new patient presenting for diagnosis and treatment at the Out-Patient Medical Clinic. After taking a careful history and making the physical examination in detail, he sees the patient with one of the staff. After a thorough discussion of the problem and a review of the findings, a decision is reached as to disposition of the patient, i.e., whether the patient should be admitted to the hospital, what further

laboratory or x-ray studies are desired, etc. On the patient's next visit to the Out-Patient Clinic, he will be seen by the same student and staff member who will again attempt to arrive at a definite diagnosis and plan of therapy It may be that a third visit will be required because additional laboratory work or x-ray studies are necessary. Often the patient can be discharged to return to the local physician. In this event, the student prepares the letter to the referring physician, which is reviewed and signed by the staff member. This system provides continuity in follow-up.

In addition, the Department of Medicine is responsible for the admissions service of the hospital. All new patients are worked up either through the system just referred to or, if emergencies, by the medical intern and fellow on call in the admissions room of the hospital.

The staff of the Department represents a number of interests in the broad field of Internal Medicine, and it should be emphasized that every effort is made to sustain the philosophy of internal medicine as a broad discipline in which the patient is regarded as a whole and not from the standpoint of narrow, segregated specialties . There are no specialty services in medicine at the University Hospital. It is true that one of the services in the Variety Club Heart Hospital places more emphasis on cardiovascular disease but students, both undergraduate and graduate, and staff rotate through all services so that a broad integration is maintained.

Research activities in the department are on a rather broad scale. These include studies of brucellosis, staphylococcus infections, chemotherapy, various aspects of liver disease, pigment metabolism, coagulation mechanisms, hypertension (both therapy and fundamental aspects), electrocardiography, metabolic problems, cancer biology, and steroid and mineral metabolism. The fellows in the department are invited to conduct research in collaboration with graduate advisors or with their supervision and advice, either in the areas which have just been mentioned or along some other avenue which is mutually acceptable.

Teaching, service to patients, and research are co-ordinate and interdependent activities in the Department of Medicine as they are in other clinical departments. Each week the department holds a number of conferences and seminars as well as ward rounds. All physicians are cordially invited to attend any of these sessions.

ROCHESTER DOCTOR RECEIVES NATIONAL AWARD

Dr. Frank H. Krusen, Rochester, Minnesota, received the Presidential Award of 1953 for his contributions to the employment welfare of the handicapped.

The citation was presented to Dr. Krusen at the annual dinner of the Industrial Health Congress in Louisville, Kentucky, February 24 and 25. Dr. Krusen received the award from Dr. Ross T. McIntire, Washington, president of the President's Committee on Employment of the Physically Handicapped.

In accepting the award, Dr. Krusen said that "proper restoration of handicapped persons depends on three things: (1) appropriate; definitive treatment and physical rehabilitation of the handicapped person in the hospital; (2) proper vocational rehabilitation, and (3) well-established programs for employment of the handicapped." Dr. Krusen is head of the section on physical medicine at the Mayo clinic.

New Light on Problems

The 14th annual Congress on Industrial Health featured discussions of wide interests to physicians, management representatives and labor leaders. Problems encountered in the maintenance of the health of factory and white-collar workers were topics of interest to those attending. Panel subjects included the stress effects on workers in industry, covering disorders such as neuroses, heart conditions, and ulcers; the effect of prolonged illness occupied another panel subject; the preventive medicine program carried out in some of the duPont plants; industrial implications of emphysema, including the clinical aspects, pathologic physiology, histopathology, radiography and therapy; the difficulties of small plant operators in providing medical care.

Improvements Noted

Frank G. Dickinson, Ph. D., Chicago, director of the AMA's Bureau of Medical Economic Research, reported that improvements in medical service have greatly increased the economic value of industrial workers. Said Dr. Dickinson:

> "In 1900, perhaps one-half of the industrial workers twenty years of age could expect to live to the age of sixty-five. Now, more than four-fifths of them are destined to reach that retirement period.
>
> "The decline in mortality during the working years of life has contributed greatly to economic progress. It has contributed to the solution of some social problems—the probability of becoming an orphan, for instance, has been cut in half."

A joint conference of the Council on Industrial Health and chairmen of state medical society committees on industrial health was held on the day before the opening of the congress. The meeting was sponsored by the American Medical Association's Council on Industrial Health, and physicians and others from the entire country attended to hear of these important phases of industrial health and medicine.

UNION HEALTH PLANS GET "ONCE-OVER"

A greatly intensified interest in health and welfare plans of labor unions has sprung up within recent years. An excellent example of this interest is seen in a new survey published by the American Medical Association called "Union Health Centers." This survey traces the growth of present plans and notes in the introduction that during and since World War II a much broader and deeper system of such plans has been growing.

It is interesting to note that the pros and cons of such plans have also been presented recently by the *Wall Street Journal.* In a series of articles on the Teamsters Union, the *Journal* states:

> "A deep concern for 'health and welfare' has seized leaders of the giant Teamsters Union.
>
> "In the brief period since World War II they've rushed to arrange a bewildering variety of insurance and direct medical service programs."

The article goes on to relate that the interest does not confine itself to the unions themselves, but is manifested in local grand juries and by no less than three Congressional committees. Most of this interest is directed toward finding out about the disposition of certain union funds. One such investigation is being made into the Labor Health Institute in St. Louis, whose finances are being questioned.

According to the *Journal*:

> "The institute has its own elaborately equipped five-story clinical building where union members and their families can get their teeth fixed, have allergies treated, their throats sprayed, their bones x-rayed, and buy drugs. It finances service in hospitals, as well. Nearly a million dollars annually is paid in by 175 companies and employer groups whose contracts with the union provide that either 5 per cent or 3½ per cent of their gross payrolls shall go to L.H.I. The larger figure appears in contracts providing full coverage for the dependents of union members."

No Trouble Elsewhere

While the *Journal* goes into detail about union leaders being jailed for failure to produce books on health plans, another similar plan, with infinitely different purposes and consequences, has been reviewed. The *Wall Street Journal* itself has featured a story about a mass check-up which is praised by firms, unions and employes in Los Angeles. Called a project in preventive medicine, the plan consisted of one thousand workers at two manufacturing plants being given comprehensive, on-the-job physical checkups that didn't cost them anything. In the *Journal's* words:

> "Hoffman Radio Corp.'s television division, with 500 employes, and its neighbor, Leach Relay Co., Inc., with an equal number of workers, offered the health survey as a means of ferreting out prevalent, but often unrecognized, ailments ranging from defective vision to heart trouble or lung cancer."

The company's personnel manager praised the plan: "It's a benefit to the employes, and we believe in the long run it will also benefit the company in terms of better employe relations and reduction of lost time due to illness."

Medical Support Given

The idea for the mass employe health screening came from the University of California at Los Angeles, which suggested it to union representatives. It was tried without fanfare and turned out to be successful enough to warrant a thorough test. The *Journal* reports:

> "An unusual demonstration of community teamwork by local health organizations kept the actual cash outlay for the survey to $500—or $100 apiece from each of the two companies and the three unions."

Participating organizations and their contributions were: American Cancer Society (pamphlets, and review of some chest x-rays); California Department of Health (equipment for blood tests); Los Angeles City Health Department (equipment and medical advice); Los Angeles County Diabetes Association (equipment, and blood sugar tests at minimum cost); Los Angeles County Heart Association (educational material, electrocardiograms); Los Angeles County Medical Association (co-ordination of projects); Los Angeles County Tuberculosis and Health Association (x-ray equipment, film, technician); University of Southern California Research Laboratory (co-ordination of diabetes tests); University of California at Los Angeles (its Institute of Industrial Relations acted as catalyst in getting companies, unions and other agencies together).

The plan drew favorable comments from all of those participating, union officials, company officials, agency officials and employes themselves. The plan was a sample of what can be done if all concerned work together to promote a worthy project for the good of all. Those who worked out the project feel that if used in other areas, care should be taken to see that all agencies are in on it and that all have a part in planning and operation.

COMMISSION BRINGS RECOMMENDATIONS

The Commission on Financing Hospital Care has recently published its recommendations, after two years of intensive study and investigation. The thirty-four member commission completed its study with contributions amounting to $556,000 from the Blue Cross commission, Health Information Foundation, John Hancock Mutual Life Insurance company, W. K. Kellogg Foundation, Michigan Medical service, Milbank Memorial Fund, the National Foundation for Infantile Paralysis and the Rockefeller Foundation.

Pointing out that in eight states three-fourths of the population are participating in voluntary prepayment plans for defraying hospital expenses, the Commission states:

> "The financing of hospital care and the maintenance of standards of hospital service will depend increasingly upon maximum coverage of the population with voluntary prepayment at the lowest possible cost compatible with the inclusion of adequate benefit provisions."

The Commission report then goes on to make the following recommendations:

1. Hospitals should take the initiative in establishing local study committees to evaluate all prepayment plans in their area. Recommendations for improvement should be made to the prepayment agencies, the hospitals and the public.

2. Prepayment agencies should take the initiative in mobilizing community leadership to inform the public concerning the frequency of hospitalized illness, the rôle of voluntary prepayment in meeting costs, factors affecting cost, and benefit provisions.

3. Methods should be developed to enroll the following who are not presently covered by prepayment in sufficient number: dependents of present contract holders such as infants, children over 18, parents and other relatives; the self-employed; farm operators and employes; employes of small firms; employes who retire under pension plans; employes temporarily without employment because of short layoffs or change of employers; domestic employes; migratory workers; persons receiving workmen's compensation benefits.

4. Employer participation in costs of prepaid protection should be encouraged.

5. Methods should be explored for the coverage of individuals and families by prepayment during periods of temporary unemployment.

6. Methods should be explored for continuation of coverage during periods of prolonged disability.

7. Programs might be developed for coverage of individuals and families who are without income from employment.

8. Low-income families should be encouraged to budget through prepayment for the cost of adequate protection. Experimental programs should be instituted to reduce the cost of prepayment to bring protection within reach of this group.

9. Hospitals, prepayment agencies and community groups should support, promote and interpret administrative practices in the operation of prepayment which help attain maximum coverage.

10. Hospitals and community groups should aid in enrollment policies and techniques to permit those not covered to attain prepayment protection.

11. Hospitals should help conduct area-wide studies of prevailing benefit provisions and their effect upon the financing of hospital care. Recommendations should then be made to the public regarding basic benefit provisions required for adequate protection of public and hospitals.

12. Hospitals, co-operating with others, should assume leadership in developing measures and educational programs designed to assure most efficient and economical use of prepayment funds. Consideration should be given to efficiency in provision of hospital services, unnecessary use of hospital services, appropriate use of hospital services and efficiency in operation of the prepayment agency.

OFFICE HEMATOLOGY

(Continued from Page 279)

The majority of stain trouble is *buffer* trouble. We use the following buffer adjusted to a pH of 6.4: potassium phosphate, monobasic, 6.63 gm.; sodium phosphate, dibasic, anhydrous, 2.56 gm.; distilled water to 1,000 cc. Check the pH of the buffer frequently with several crystals of hematoxylin in a test tube of buffer solution. A pink-lavender color develops in two minutes if the buffer is satisfactory. Red-purple means it is too alkaline; yellow means it is too acid. Adjust with weak acid or bicarbonate as indicated. The stain-buffer times varies with each new batch of stain. A good stain is pink on the slide. Erythrocytes should be light buff; the nuclei are blue-purple and are in sharp contrast to the cytoplasm. Eosinophilic granules are bright red and neutrophilic granules are pink to lavender.

No degree of diagnostic acumen can correct for a poor smear or a poor stain. When sending blood smears for consultation, send one stained and one unstained smear with pertinent clinical and hematologic data. Give the age of the patient. Bone-marrow preparations require exacting and special technique and are not office procedures. It's not "old fashioned" to look at your own blood smears. You cannot afford to ignore them!

SPONTANEOUS RUPTURE OF THE LIVER

A Case Report with Recovery

L. A. STELTER, M.D., and G. L. PETERSEN, M.D.
Minneapolis, Minnesota

THE FIRST known case of spontaneous rupture of the liver was reported by Vesalius at some undetermined date. Andral, in 1829, sketchily reported two cases with complicating lesions which may have been gummata or carcinoma. However, in many of these earliest cases, there is some probability that gastric hemorrhage, secondary to liver disease, may have been mistaken for actual rupture of the liver. According to Devic and Beriel and later Mazel, the following theory had been formulated: "In traumatic rupture, the rupture is the cause of hemorrhage. In spontaneous rupture, the hemorrhage is the cause of rupture."

Rupture of the liver is a result of spontaneous tearing or trauma. The chief traumatic causes are: (1) blunt force, (2) open injuries, such as stab wounds, gunshot wounds and war injuries.

Of all the organs in the abdominal cavity, the liver is the most likely to be injured when the abdomen is hit in any part by blunt force. Street and automobile accidents; falls from scaffolding; burying accidents; war injuries and hoof beats are the main causes. In 494 postmortem examinations of rupture of abdominal organs through blunt force, liver rupture rates first with 59.9 per cent. The right lobe has been found ruptured much more frequently than the left. The relationship is about 65 to 35.

Spontaneous rupture of the liver is due to enlargement of the liver from disease within stretching Glisson's capsule, which has a certain degree of tension. The chief diseases which may cause the liver to burst are fatty degeneration, malaria, tuberculosis, syphilis and malignancy. It occurs when the liver is more friable and during digestion when it becomes hyperemic and enlarges.

The greatest danger in liver rupture is hemorrhage. In fact, this is the main cause of a fatal outcome. The large intrahepatic veins have very thin walls, no valves are present, and there is no retractibility, therefore the bleeding is persistent and spontaneous control is rare. Because of the large venous blood supply in the liver, the hemorrhage is more likely to be of venous nature and enormous amounts of blood may be found in the abdominal cavity.

Extensive liver injuries have a very high mortality rate and statistics from the war give a lower mortality rate (60 to 80 per cent), which may be erroneous, as a considerable number die immediately on the battle field because of massive hemorrhage.

Clinical signs of ruptured liver and differential diagnosis are: (1) symptoms of general shock, (2) general symptoms of abdominal injuries, (3) special symptoms caused by the injured liver.

Shock. The patient lies still with an expression of fear in the face. The skin is pale and clammy; the mind is clear, but mental activity is diminished. The respiration is shallow and frequent, deep sighs interrupting normal respiration. The pulse at first is full and bounding, later thready and rapid, and the blood pressure progressively falls.

Special Signs of Liver Injury. When loss of blood occurs in the abdominal cavity, peritoneal irritation occurs immediately, the intensity depending on the rapidity of intra-abdominal hemorrhage. Pain after rupture of the liver, is quite characteristic. It is especially felt when pressing the finger into the intercostal space. Pain radiates downward and backward and also into the right shoulder. This referred pain is due to diaphragmatic irritation through the phrenic nerve and into the cutaneous branches of the dorsal scapular nerve. Breathing is shallow, more fre-

TABLE I. CAUSES OF RUPTURE OF THE LIVER OTHER THAN VIOLENT MUSCULAR EFFORT*

quent, and may be painful. Dullness in the right side of the abdomen gradually increases and spreads downward as the blood flows down the right abdominal gutter. The dullness may shift if the patient is turned to the left. Rectal or vaginal or rectovaginal examination reveals fullness in the pelvis and tenderness. Bradycardia may last longer than in other types of intra-abdominal hemorrhage and this is due to resorption of bile from the abdominal cavity. Bile salts have a depressing influence on the heart. Diagnosis of bile salts may be made by tapping the abdominal cavity with a No. 20 spinal needle; a procedure which I have done on various occasions of abdominal injury or suspected ectopic pregnancy. No harm will be done to the small or large bowel where the abdomen is free from adhesions. The examination of the blood for bile and bile salts and for liver cells will be helpful. X-ray examinations, upright and flat abdomen, will only help in ruling out air under the diaphragm in rupture of gas containing viscera. Auscultation reveals a near silent abdomen.

Complications. (1) death from hemorrhage, (2) cholascos (effusion of bile into the abdominal cavity) causing bile peritonitis, (3) permanent biliary fistula, (4) infection of the liver wound, (5) embolism of liver tissue, (6) infarction of the liver, (7) lung complication—pneumonia (due to emboli), (8) hepatorenal syndrome (nephrosis of the kidneys), (9) eye symptoms, simulating albuminuria retinitis.

Treatment. From the statistics of Elder, Terrier, Auvray and others, who have shown that the mortality in non-operated cases was as high as 85.9 per cent, while in the past decade, with modern surgical intervention, the mortality has been reduced from 53.8 per cent to 28.5 per cent, we feel that this is an acute urgent surgical entity. The patient should be transfused by multiple portals of blood and operated upon immediately.

Case Report

The patient, a white female teacher, aged twenty-three, a student at summer school, gave the following history: While eating her Sunday dinner with a friend at 2:00 P.M., she was suddenly stricken with an acute pain in the right shoulder. She was unable to finish her meal and had to be assisted to a lounge where she lay for a short time having a lady massage her shoulder because of the pain. She then experienced pain in the upper abdomen—severe and intense—vomited her dinner and retched several times, after which she felt relieved for about an hour. During this time she was taken to her room, at a Girls' club, and went to bed, complaining to her roommate that her abdomen was getting more and more painful, that she felt faint and weak, wanted to vomit, and that she had a severe backache.

I saw the patient at 5 o'clock p.m., a tall, fairly well-developed female, holding her hand on her upper abdomen. She was somewhat pale, the examination revealed she had a normal pulse, blood pressure was 70/30, heart and lungs were normal, abdomen was held tense and with boardlike rigidity above the navel and across to the right lower quadrant. Vaginal examination was negative. She was sent to Fairview Hospital by ambulance and upright and flat x-rays revealed no air under the diaphragm. Hemoglobin—70 per cent; R.B.C.—3,700,000; W.B.C.—16,000; P.M.N.'S—94 per cent; lymphocytes—6 per cent. Urinalysis revealed sugar—four plus also acetone and diacetic acid. There were 40-50 R.B.C.s and pus cells—20-30 per high powerfield pus cells. Re-examination of her abdomen at 8 o'clock p.m. by Dr. Petersen and myself, revealed a benign abdomen. There was no rebound tenderness and no rigidity at this time. The patient laughingly remarked, "Why do I have to stay in the hospital? My pain all left me when I came here in the ambulance."

We decided to treat the patient conservatively on the basis of a diagnosis of sealed perforated posterior duodenal ulcer, complicated by a severe diabetes and pyelitis. Nasal suction was instituted and Dr. Petersen treated the diabetes by I.V. glucose and large doses of insulin. Re-counts of laboratory work were ordered for the following morning. Her blood pressure and pulse were observed at hourly intervals during the night and no change was noted. At 7:30 a.m. the next morning no change was noted except for some abdominal distention. On rectal examination some fullness was felt in the lower pelvis. Re-check of x-rays and I.V. pyelogram were ordered.

At 11 o'clock a.m. an acute change in her condition was apparent. The pulse became rapid. She had become pale and clammy. The vaginal examination, at this time, revealed marked tenderness. I then made a diagnosis of acute abdominal catastrophe, as the laboratory at this time, reported that her hemoglobin had dropped to 55 per cent and the red blood cell count was 2,500,000. A diagnosis of intra-abdominal hemorrhage was evident. An emergency operation was performed.

Under spinal anesthesia, with two units of bloods and normal saline running in the veins, a "peak" right paramedian incision was made. On finding the abdomen full of blood, the incision was continued down to the pelvis and both tubes and ovaries explored and found normal. Exploring the right side and following up to the liver, I found that the girl had a ruptured right lobe of the liver. The incision was extended to the xyphoid and the right rectus muscle cut across to the right costal margin, the blood evacuated by suction, approximately 1 quart, and a rent, the size of my hand, was found in the right lobe, extending up to the dome of the liver. The entire surface of the right lobe was dark from subscapsular hemorrhage and echymosis. The active bleeding, which was profuse from the liver rent, was then controlled by large gauze packs. These were then gradually removed after the patient's pulse and blood pressure stabilized and replaced by oxycel and gel foam, seven such packs were used to fill the rent and the liver was then sutured with mattress sutures. This, however, proved very difficult because of the friability of the organ. Two large cigarette drains were placed between the chest wall and the liver rent and the abdomen was then closed, the peritoneum with chromic 0 doubled, the fascia with through and through wire and cotton. A third transfusion was given after surgery and her immediate postoperative condition was good. Her postoperative progress was satisfactory and her diabetic condition was controlled by I.V. fluids and insulin under Dr. Petersen's supervision. Nasal suction was continued.

A liver biopsy, at the time of surgery, was considered and would have been helpful, but in view of the critical condition of the patient, and the black, discolored liver tissue, I felt the procedure would only add insult to an already badly injured organ.

The remaining postoperative condition of the patient progressed satisfactorily. After the third day, the nasal suction was removed. One drain was removed on the fourth day and the second on the eighth day. The patient left the hospital on the thirteenth day postoperatively and was seen subsequently in the office.

A letter from her on the second month after surgery, reported her to be in fine physical condition.

Comment

In 1943, Rademaker collected twenty-nine cases of spontaneous rupture of the liver, including the case of Vesalius. Since then four cases have been added, three associated with pregnancy and one with hypertension.

Because a biopsy of the liver was not made at the time of surgery, I believe one is justified in assuming that this case of spontaneous rupture was due to some metabolic disturbance of the liver, associated with a mild diabetes.

Minnesota Department of Health

GAMMA GLOBULIN (IMMUNE SERUM GLOBULIN)

For Poliomyelitis

Gamma globulin is available for direct intimate contacts, forty years of age and under, of reported cases of clinical poliomyelitis on receipt of the name, age and weight of the contact, and identification of the case of polio. The dose of globulin for poliomyelitis contacts is 0.14 cc of globulin per pound of body weight, to a maximum of 20.0 cc and should be given as early as possible following exposure. It is probably of little value if *ten* days or more have elapsed after exposure.

For Infectious Hepatitis

Gamma globulin is regularly available for close and continued contacts of cases of infectious hepatitis (jaundice). Since the product is of no value once symptoms of the disease have begun, and even late in the incubation period, this means that the product should be used largely in household contacts and those living in small groups where the contact is essentially the same. The dose of globulin for contacts of infectious hepatitis depends on the body weight and is 0.02 cc of globulin per pound of body weight, with a maximum of 2.0 cc for any one individual. Globulin should be given to all household contacts who do not give a history of having had the disease, including adults.

For Measles

Gamma globulin for measles has been available for a number of years and most physicians are familiar with its use for this purpose. Those at greatest risk are children three and under. As a general rule, the amount given is aimed at modification of the disease and the development of permanent immunity by a mild attack. Occasionally it is wise to aim at complete prevention, even though no permanent immunity results. Only contacts who have had a recent definite exposure should receive globulin. Those who have had measles already should not be inoculated.

For modification, the dose of globulin for children definitely exposed to measles is 0.02 cc of globulin per pound of body weight. When given during the first six days following exposure, this amount will usually produce a modified case of measles. If complete prevention is urgent, the dose is five times as large. Gamma globulin should not be given if ten days or more have elapsed after exposure, since its value at that late date is negligible.

For Other Conditions

Globulin is not distributed for other conditions for which its value has not been established. This includes mumps, german measles, diarrhea, or for treatment of symptoms once a disease has developed.

Reporting of Cases

Since the Department's supply of gamma globulin is allocated on the basis of numbers of reported cases, it is important that all cases of the above diseases be reported to the State Board of Health as required by regulation.

LABORATORY EXAMINATION OF GASTRIC WASHINGS FOR TUBERCLE BACILLI

Increasing numbers of patients with tuberculosis are receiving post sanatorium out-patient chemotherapy, extending over long periods. It is important that such patients have careful evaluation of their progress at intervals of three months or so, including x-rays, laboratory studies, and tests for the presence of tubercle bacilli. Usually the latter tests are performed by culturing the gastric washings of the patient.

When gastric washings are collected for culture for tubercle bacilli, the specimen should be immediately put into the special bottle prepared for this purpose. This bottle contains a buffering chemical which neutralizes the acid in stomach washings and inhibits the detrimental action of the gastric acidity on the tubercle bacilli. Unless this is done, the bacilli are soon killed and cultures will show no growth.

The Minnesota Department of Health furnishes these special outfits for the mailing in of gastric washings for culture and urges that the special outfit be used whenever there is to be delay between the collection of the specimen and its inoculation onto culture media in the laboratory.

FATIGUE AND HEALTH

There seems to be little doubt that physical and intellectual fatigue, as well as painful emotions, decrease resistance of the body to infection; but the physiologic mechanisms which determine these important relationships are totally unknown. Despite all this ignorance, however, a belief shines as a beacon to guide our efforts. It is that the defense mechanisms of the body which promote resistance to infection appear to be closely related to the physiologic processes which make for good health—good health being here measured in the terms broadly referred to as well-being by the layman. The inner logic of the program of antituberculosis associations should lead them to become truly health associations. For it can hardly be doubted that, in final analysis, health is a positive attribute rather than merely the absence of disease.—René J. Dubos, Ph.D., American Review of Tuberculosis, July, 1953.

MEDICAL HISTORY OF THE COUNTY OF YELLOW MEDICINE

MILDRED B. LEE
Granite Falls, Minnesota

(Continued from March, 1954, issue)

William Moffat Stratton was born in St. Lawrence County, New York, in 1844. His education began in the common schools of that state, and continued in the schools of Wisconsin when the Stratton family moved west in 1854. He received his medical training at Ann Arbor, Michigan, and at Chicago Medical College which is now a part of Northwestern University. He graduated from the latter school in 1869.

Soon after graduation Dr. Stratton began practice at Ortonville, Minnesota. In 1873 he moved to Minnesota Falls, which was a new settlement on the south bank of the Minnesota River just above Minnesota Falls in Yellow Medicine County. Here he was joined by another physician, Dr. E. N. Falk, and although the two doctors did not practice as partners they were partners in a drug business which they established and carried on for several years.

Drs. Stratton and Falk were both graduate pharmacists as well as physicians.

When Dr. Stratton came to Minnesota Falls the little town was competing for the honor of being named the county seat, and it had made astonishing progress in the short time it had been in existence, boasting a flour mill, hotel, blacksmith shop, two stores, a law office, and several saloons. A newspaper would add to the town's prestige, and Drs. Stratton and Falk became partners in establishing the first newspaper in Minnesota Falls and in the County, the *Minnesota Sentinel.* The first issue appeared October 1, 1874.

The paper was a modest effort; it was a six-column folio with the outer pages filled with local advertisements, some in Norwegian, professional cards of the doctors and lawyers, legal notices, and local news items. The few copies which are on file in the office of the clerk of court contain tax lists, and also a fairly full account of a libel action brought by Dr. N. M. Smith against Editor Hogue of the *Granite Rock.* In 1876 the *Sentinel* was sold to a Mr. Bennet who kept it in publication for another two years, after which it died from lack of support.

When Granite Falls became the county seat the population of Minnesota Falls began to move away from the town. Dr. Stratton moved to Granite Falls about 1877 or 1878, and became a member of the first town council in 1879. In 1881 he became president of the council, and later served as Health Officer of the city and as a member of the Board of Education. In the latter capacity he was one of the board members who chose the site for a school in West Granite Falls, and brought about the erection of the first school building on the present school grounds.

Dr. Stratton married Adeline Sarah Enos, whose father was a carpenter and built many houses in Granite Falls. One of these, Number 235, on Tenth Avenue, is now the home of Paul D. Stratton. Dr. Stratton himself lived in a house on south Prentice Street which is still standing, though somewhat altered, as No. 1165 Prentice.

When he first came to Granite Falls, Dr. Stratton became a partner of Dr. Cyrus P. Fuller who was the first physician to locate in Granite Falls.

Dr. and Mrs. Stratton were kindly, generous people who became popular residents of the village. In youth they were considered a rather handsome couple. Dr. Stratton was of average height, having a rather round face with large and slightly protruding eyes, a full lipped and usually smiling mouth. He walked with a slightly shuffling gait and always carried an umbrella—his own or someone else's; and it was usually in varying states of dilapidation; he liked to have something to carry as he walked along. Usually he walked with down-bent head and his manner was quiet and kindly. He had a keen sense of humor. In temperament he was easy-going; although he kept an extensive set of books he never pressed anyone for payment, and indeed seemed to be indifferent not only to obligations owed to him but to those he himself owed. He was devoted to his patients. He would answer calls at any time of day or night and give freely of his time and effort. Sometimes he suffered keenly over the death of a patient. He was a physician and surgeon of exceptional ability, and neither weariness nor other circumstance ever seemed to affect his skill and judgment in reference to medical practice. Educated in a time when the germ theory was unknown he never adapted himself to new techniques of sterilization and sanitation.

Dr. Stratton practiced under most primitive conditions. The doctor's offices had none of the conveniences essential to comfort. A wood burning stove furnished heat, water was carried in, illumination was furnished by coal oil lamps; and unless the doctor was lucky enough to be able to employ help the doctor did what janitor work was required. Like other pioneers he got around the country as best he could; by horseback, with horse and buggy, sleigh or cutter. For many years Dr. Stratton and Dr. Flynn of Redwood Falls were the best known, if not the only doctors in a very large territory, and they were on the road day and night. At one time Dr. Stratton owned seven horses and it is remembered that Mr. Charlie Rice drove for him. A driver was a necessity not only to share the labor of getting the buggy through mudholes or snow banks but to permit the doctor to rest between calls.

When the railroad came to Granite Falls in 1878 Dr. Stratton was appointed the first surgeon and physician of the road at that point, and he held this post until his death, so that he was then the oldest physician of the line in point of service. Soon he began to travel by train to the more distant points to which he was called; the *Granite Falls Journal* mentions that "Dr. Stratton is on wheels most of the time," attending to his practice, and meeting in consultation with other physicians.

The Stratton home was a favorite meeting place for the children of the neighborhood. Dr. and Mrs. Stratton had a family of their own: three sons, Frank E., William, and Paul D., and three daughters, Adeline E., Edna, and Susie. Susie loved to help her father; she is remembered as a little girl with braids down her back and glasses on her nose, using the vaccinating needle like a veteran upon the children who were candidates for this rite. But it was Edna, not Susie, who became a nurse.

The Strattons had their sorrows; the little girl, Adeline, died in 1894; the doctor's health suffered and he was away for five months for treatment and rest. Younger doctors with more modern methods and techniques settled in Granite Falls and other parts of the county which he formerly served, cutting into his practice; and in his later years the doctor had less strength for and interest in the arduous duties of the country practitioner. Throughout his career he was respected for his exceptional skill and medical knowledge, for he often succeeded where other physicians failed. His personality endeared him to all who knew him; he brought to his patients the assurance of his sincere interest and concern.

When plans were made for the erection of a tubercular sanatorium at Granite Falls for the tubercular patients of three countties, Dr. Stratton was chosen as a member of the board from Yellow Medicine County, and this position he held during the time the buildings were being erected and the first patients received at the new sanatorium. He was also a member of the Camp Release Medical Society and of the State Medical association.

Mrs. Stratton died January 11, 1912, after a rather long period of declining health. Dr. Stratton died November 10, 1916, of a stroke of apoplexy, at the age of seventy-two years. He was survived by his sons, Frank E., William, and Paul D., his daughters, Edna Maercklein, and Susie (Mrs. M. H.) Geehan. Edna Maercklein was the wife of a doctor and assisted in the operation of a hospital at Oakes, North Dakota, at one time.

Present survivors of the Stratton family are Paul D. Stratton, an attorney who has practiced at Granite Falls for about forty years; Susie, who was Mrs. M. H. Geehan of Graceville, Minnesota, was survived by a son, Robert Geehan, who is a mining engineer, and a daughter Adeline who is now employed by the city of Minneapolis.

Albert R. Torgersen

"Dr. A. Torgersen of Fargo, North Dakota, is stopping at E. P. LeSeuer's Drug Store. He has had extensive experience and will gladly attend any demands for his professional services."

This announcement in the issue of the *Canby News* of October 9, 1885, heralded the arrival of Dr. Albert R. Torgersen, who was to spend many years in the practice of medicine in Yellow Medicine County.

Albert R. Torgersen was born in Oslo, Norway, and received his education and medical training in the schools and Universities there. He came to the United States as a young man and settled first in Wisconsin. From Wisconsin he came to Minnesota, locating in Alexandria, where he met the young woman who became his wife, Miss Addie Corneliuson, who was also of Norwegian descent. From Alexandria he went to Fargo, North Dakota, leaving that city for Canby in 1885.

When Dr. Torgersen came to Canby he had two children, Rudolph Charles, who was born in Alexandria, and William Cornelius, who was born at Fargo, North Dakota. In appearance the doctor was small in stature, dark, always well groomed and giving an impression of poise and good breeding. He wore a large mustache, and in disposition was kindly, but very outspoken and so strong in his convictions that he was sometimes regarded as "contrary."

Dr. Torgersen seemed to have trouble establishing himself in Canby. A rumor to the effect that he was not qualified to practice in the state caused at least one patient to refuse to pay for his services, and Dr. Torgersen promptly sued for his fees. Thereafter he announced through the *Canby News* that he had been educated in Norway and had complied with the requirements of state law and was licensed to practice in Minnesota.

Dr. Torgersen was also a graduate pharmacist, and after three years in Clarkfield, during which time another son, Roy Jay, had been born, the doctor decided to go into the drug business in connection with his practice. In 1888 he purchased the stock of the Clarkfield Drug Store and on September 20, the *Canby News* announced that "Dr. Torgersen has taken possession of the drug store he recently purchased at Clarkfield. He will probably do well in his new venture and the outlook is flattering." As to what Clarkfield was like at this time, there is this comment:

> "Clarkfield is a new town started upon Monson's place two years ago and now numbers 300 inhabitants. It is a great wheat market for a town of its size and has taken in as high as 5,000 bushels of wheat a day. Yellow Medicine must be a wheat growing county, one 20 acre piece yielding 900 bushels of Blue Stem wheat."

The little village was in the heart of a rich farming country and its population was predominantly Norwegian. Dr. Torgersen was the first doctor to locate in Clarkfield.

The doctor's first offices in Clarkfield were in the old Myhre Building, and his family lived in the rooms adjoining them. Shortly after the arrival in Clarkfield another son, Cleve Reuben, was added to the family circle. The doctor was a Democrat and a great admirer of Grover Cleveland, and Cleve Reuben was named for him; but during Cleveland's administration the doctor suffered heavy financial losses, as did many other business and professional men, in the panic of 1893.

In 1888 Dr. Torgersen was elected county coroner; and he was very conscientious in exercising the duties of this office, as shown by the case of Peter Strand. In this case the dead man was found in a meadow where the body had evidently lain for some time undiscovered, despite the fact that one Luders had been mowing in full view of the body for some days. A quantity of blood, or evidences of blood, was found, and there were wounds in the throat. But the man was buried in spite of protests, as he was an immigrant and without friends, but believed to have had money as he contemplated buying a farm. Evidently public opinion compelled the authorities to take further steps, so the body was exhumed and an examination made. The *Canby News* reported that the doctor felt he had "been hindered in his examination," and believed that murder had been done, but the authorities refused to take action. The county attorney was A. J. Volstead.

Dr. Torgersen also served as County Physician for the Clarkfield medical district.

The fifth child born to the Torgersens was Pearl Celia, and when the little girl was still very young her mother died very suddenly.

After this bereavement the doctor was left with the responsibility of caring for the children in addition to his medical practice and drug business. Nevertheless he managed; the family lived in a home in the west part of Clarkfield where the doctor had an opportunity to indulge his hobby of gardening. During the summer his vegetable garden and gorgeous flower beds made his home a show place. He also found time for crayon work and drawing which showed his considerable talent as an artist.

The rewards of medical practice in this small community were small. The usual charge for a confinement case was $5.00; a country call was made for $2.00, and a dollar had to be paid out for a livery rig. Then often the farmer would tell some story of hard luck, and Dr. Torgersen would tell him just to forget about the fee. People respected Dr. Torgersen's ability as a doctor, and although new and younger doctors came to the community there were many people who thought no one could do quite as much for them as Dr. Torgersen.

The doctor's son Rudolph Charles answered the call for volunteers in the Spanish American War, and shortly after his discharge from service died in Seattle, Washington.

Another boy to go into the military service was Cleve Reuben, who served in World War I, and was killed in action.

In 1917 Dr. Torgersen gave up the practice of medicine in Clarkfield and went with his son Roy Jay to Hawarden, Saskatchewan, Canada, and lived there until his death.

He was survived by his son William Cornelius, who is now in business in Starbuck, Minnesota; Roy Jay who is in business in Winnipeg, Canada, and Pearl Celia (Mrs. A. G. Drysdale) who resides in Arcadia, California.

William B. Torgerson was born in Worth County, Iowa, on October 27, 1872. He was the son of Rev. Torger A. Torgerson and Dina Anderson Torgerson, and was christened Wilhelm B. Torgerson. He received his early education in the schools of Iowa, and then entered the College of Homeopathic Medicine and Surgery of the University of Minnesota. He graduated in 1897, and began his practice in Cannon Falls, Minnesota, the same year.

In November, 1908, Dr. Torgerson located in Clarkfield. The *Cannon Falls Beacon* in commenting on Dr. Torgerson's departure stated:

> "Dr. Torgerson's departure will be greatly regretted. He is a thorough gentleman and a skilled physician who has gained many friends during his stay in Cannon Falls."

In Clarkfield Dr. Torgerson occupied offices over the Clarkfield State Bank, with living quarters in connection so that he could be conveniently "found day and night" as stated in the *Clarkfield Advocate.* He was a tall, slender, dignified young man, with brown hair and eyes, a small well trimmed goatee, and is generally described as "aristocratic looking."

In 1899 Dr. Torgerson was appointed Health Officer for the village of Clarkfield.

In June, 1900, Dr. Torgerson took a brief vacation, during which, on June 14, he was married to Miss Ingeborg Johanna Ohnstad of Watsedo, Minnesota; ("the bride is one of Goodhue's fairest and most accomplished daughters") and the young couple returned from a wedding trip to take up housekeeping in the apartment formerly used as offices and living quarters, while the doctor settled in new offices over the bank. According to the *Advocate,* Dr. Torgerson "came here about two years ago, and by strict attention to his profession has built up a good practice and enjoyed a large degree of popularity in social circles."

Throughout his life Dr. Torgerson was known as William B. Torgerson rather than by his baptismal name of Wilhelm.

The first child born to the Torgersons was a girl, born May 14, 1901, and named Dora. A son, Erling A., was born October 28, 1902, Harold W., born March 27, 1905, and Theodore A., born May 22, 1907.

During the period of residence in Clarkfield the doctor and his wife were very well liked, and he enjoyed a good medical practice. He also occupied for a time the position of postmaster of Clarkfield.

In 1907 Dr. Torgerson removed to Greenbush, Minnesota, and practiced there until 1912. Another son, William B., Jr., was born there on February 12, 1909. In 1912 Dr. Torgerson moved to Oklee, Minnesota, and practiced there until his death.

Dr. Torgerson took an active part in public affairs in Oklee, and had many interests in addition to medicine. He went into banking, became a member of the school board, the secretary of the creamery at Oklee, and was active in church matters.

At the time of his death Dr. Torgerson was one of the oldest medical practitioners in the state. He was survived by his wife and five children. Mrs. Torgerson continues to live at Oklee, Minnesota; daughter, Dora, is Mrs. Robert E. Bilbrough of Overland Park, Kansas; Erling A. Torgerson lives at Thief River Falls where he is in business; Harold W. Torgerson lives in Evanston, Illinois, and Theodore is at Annapolis, Maryland, while William B. Torgerson resides in Oakland, California.

Dr. Torgerson was a member of the Evangelical Lutheran Church. A brother, Rev. Abel Anderson, lived at Montevideo and the Torgerson children were baptized by him and all became members of the "Synod" group of the Lutheran church.

Dr. Torgerson died July 7, 1952, of Parkinson's disease, for which ailment he was hospitalized for three years previous to his death.

Henry G. Townsend was born in Maine in 1823. He came west and it is believed that he lived for a time in Chippewa County, Wisconsin, for that was the place of residence of his divorced wife, Alice, and his son, Edgar H. Townsend.

Dr. Townsend came to Granite Falls in 1877, at the age of fifty-four years. He established himself in a house in East Granite Falls, Chippewa County, and inserted his professional card in the *Granite Falls Journal.* The issue of that paper on July 25, 1877, introduced him as a

> "Homeopathic Physician, Surgeon and Obstetrician. Special attention given to cronice (sic) diseases and diseases of women and children. Office and residence on east side opposite E. J. Fitch's Hotel."

This places him on the north side of what is now Baldwin Avenue near the Milwaukee depot.

Dr. Townsend was a quiet, elderly man; he was a member of the first library association of Granite Falls.

In 1882 Dr. Townsend had moved to Canby, where he had an office "1 door south of P. O." His professional card stated that "He will hold himself in readiness to attend calls at all hours night and day." Dr. Townsend is also said to have practiced in the small settlements near Canby more extensively than in the city of Canby itself.

On January 26, 1883, he was stricken with a heart attack and died at the age of sixty years. Probate proceedings of the county show that his only heir was his son, Edgar H. Townsend, sixteen years old, a resident of Chippewa County, Wisconsin.

M. N. Triplett was graduated from the University of Louisville in 1895, and was licensed in Minnesota January 11, 1898.

He was born in one of the southern states, either Tennessee or Kentucky, and educated in the schools of the South. He always kept his southern manner of speech, which was quite distinctive. He was a fine looking young man, of medium height and coloring, and good physique.

Dr. Triplett located in Hanley Falls shortly after his graduation and practiced there two years. At the end of that time he went to Dawson, where he built up a good practice and was regarded as a very good doctor. When he came to Dawson he had been married and was a widower; in Dawson he married a local girl, and they occupied living quarters adjoining his offices which were over Charles Anderson's store.

The doctor was friendly, well-mannered, and very well liked. He was extremely fond of hunting, and spent much time in the field during the season when it was permissible to hunt prairie chickens. He was a member of the Masonic Lodge.

About 1908 Dr. Triplett removed to Floodwood, where he bought some land, practiced medicine, and engaged in other activities. He was a member of and president of the Board of Education of Floodwood, and at one time was a member of the State Legislature. He had no children. He died December 8, 1922, of myocarditis.

James Alfred Watson was born September 5, 1867, in Longford, Ireland. He went to Canada with his father when he was seventeen years of age, and later his mother and three brothers followed. The family settled on a farm at Pilot Mound, Manitoba, and at first James Alfred Watson taught school and thus financed his medical education. He took his medical training at the University of Manitoba, in Winnipeg, graduating in 1894. He began his practice of medicine in Wood Lake, Minnesota, and stayed there four years. He left in 1898 to take up postgraduate work in eye, ear, nose and throat diseases in New York and Vienna between the years from 1899 to 1900. Returning to Minnesota in 1900 he married Lucia Coghlan of Wood Lake and began to practice as an ophthalmologist and otolaryngologist in Minneapolis. He practiced there until his death on June 17, 1939.

During his early years of practice in Minneapolis he was a member of the faculty of Hamline University Medical School.

Beginning with 1920, he practiced as a member of the Eye, Ear, Nose and Throat Clinic, and was associated with Doctors Eugene Strout, John Macnie, and W. E. Patterson. This clinic was located in their own building at 74 South Eleventh Street until the year 1934, and then in the Medical Arts Building.

Dr. Watson became a citizen of the United States soon after starting practice in Minneapolis. He was an active member of the Hennepin Avenue Methodist Episcopal Church. He was also a member of the Hennepin County Medical Society, Minnesota State Medical Association, American College of Surgeons, American and Minnesota Academy of Ophthalmology and Otolaryngology; and a member of the Minneapolis Athletic Club and the Lafayette Club.

Dr. Watson was survived by his widow and four children: Cecil James, Lelan Alfred, Eleanor Isabel, James Alfred, Jr., all of Minneapolis. He was known as a "sound and conservative practitioner of medicine and a true and kindly friend."

Dr. Watson was seventy-two years of age at the time of his death, and lived at 2100 Irving Avenue, Minneapolis. He was past president of the Minnesota Academy of Ophthalmology and Otolaryngology, a member of the Phi Rho Sigma Medical Fraternity and the Automobile Club.

Cause of death was coronary thrombosis; contributory causes, coronary sclerosis, hypertension (three years), apoplexy (one year). Burial was in Lakewood Cemetery.

Frederick G. Watson was born in Longford, Ireland. His father and his brother, James A. Watson, came to Canada in 1884, and shortly thereafter Frederick G. Watson, his mother, and two brothers followed. The family settled on a farm at Pilot Mound, Manitoba, and Frederick G. Watson received his elementary education in the schools of that province. For his medical training he entered Hamline University, graduating about 1895. He also graduated as a pharmacist, and about 1896 went to Wood Lake where he opened a drug business. On September 1, 1897, Dr. Watson married Isabella A. Tibbils of Wood Lake, Minnesota, and shortly thereafter moved to the neighboring town of Clarkfield and began his medical practice there.

Children born to Dr. and Mrs. Watson in the years that followed were: Horace Percy, born October 2, 1898; Leopold Frederick, born November 30, 1902; Sidney J., born August 10, 1904; Donald Goodwin, born October 13, 1907, and Anna Bernice, born August 12, 1909.

In appearance Dr. Watson was very English: tall, rather slender, very reserved and inclined to shyness. His speech was the clipped speech of the Englishman, a characteristic which set him off in a strongly Norwegian community. He had a very brilliant mind and was regarded as a very good doctor. He belonged to the Methodist church and his religious beliefs precluded membership in other organizations.

Clarkfield was a small village of about 320 when Dr. Watson began practice there, and had two Lutheran Churches and a Methodist Church. The language most commonly heard upon the streets at that time was Norwegian. About the same time Dr. Charles Watson, a brother, was practicing at Boyd, Minnesota, and James A. Watson at Wood Lake.

Dr. Watson built up a large practice in the community. He drove long distances to visit patients in the surrounding country, getting about with horse and buggy, or cutter, in all kinds of weather and over roads which were no more than tracks on the prairie sod, or at the best narrow highways which became almost impassible in wet weather. In 1906 his practice had grown so large that he felt it necessary to look for a partner, and the man he thought most suitable was Dr. M. M. Hauge. In 1907 Dr. Hauge came to Clarkfield as Dr. Watson's partner, and the two practiced together for some years. As Dr. Hauge spoke Norwegian fluently, was Norwegian, strongly Lutheran, and with gifts in music and other attributes which made him very popular in this predominantly Norwegian community, it was not long until Dr. Watson found his Norwegian patients preferring to consult Dr. Hauge. When Dr. Watson became convinced that there was no future for him in Clarkfield he left and located in Rushmore, Minnesota, where he stayed ten years. He then went to Worthington and established there a very good practice and a clinic.

Dr. Watson became ill with a heart ailment about 1930, and died January 11, 1932, of a heart attack, at Worthington, Minnesota.

Mrs. Watson survived him, and also his children Horace Percy, Leopold Frederick, Donald Goodwin and Anna Bernice. His son Sidney J. Watson became a doctor, graduating from the University of Minnesota Medical Department, and died prior to his father's death. His daughter Anna Bernice died July 21, 1932. Mrs. Watson died June 11, 1945, at Worthington, Minnesota.

Horace Percy Watson now resides at Sioux Falls, S. D., a partial invalid. Donald Goodwin operates a farm near Redfield, S. D.; Leopold Frederick is a dentist.

CORRECTION: Owing to an accident in the printing shop, several errors occurred in the list of licentiates as published in the February number of MINNESOTA MEDICINE. The publishers therefore are reprinting the list in its entirety in this issue to rectify the errors which appeared in the previous publication.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

230 Lowry Medical Arts Building
Saint Paul, Minnesota

J. M. Jones, M.D., Secretary

FOUR SENTENCED AT MINNEAPOLIS FOR MANSLAUGHTER FOLLOWING ABORTION

Re: State of Minnesota vs. Willard B. Peterson, Joseph E. Verhota, Vernabell Tuma and Margaret Bishop Bellanger.

On March 27, 1954, the Hon. Levi M. Hall, Judge of the District Court of Hennepin County, sentenced each of the above named defendants following their pleas of guilty, which they had previously entered, to a charge of manslaughter in the first degree, the charge arising out of the death of a 23-year-old unmarried Minneapolis woman on February 7, 1954, resulting from an abortion performed upon her on January 30, 1954, by the defendant Bellanger.

Mrs. Bellanger, 29, 1116 Como Ave. S.E., Minneapolis, an employe of a downtown bar in that city, for the past four years, who had entered a plea of guilty to the charge before Judge Hall on February 16, 1954, was sentenced to a term of not less than five years nor more than twenty years in the Women's Reformatory at Shakopee, the sentence being stayed for five years, however, and the defendant placed on probation for the same period provided she serves the first two years of her sentence in the Women's Workhouse at Parkers Lake.

Following his plea of guilty to manslaughter in the first degree on February 26, 1954, Willard B. Peterson, 37, 226 N. Van Buren, Hopkins, Minnesota, who operates a telephone answering service in Minneapolis, was sentenced by Judge Hall to a term of not less than five years nor more than twenty years at hard labor in the State Prison at Stillwater and his sentence was also stayed for a period of five years, during which time he was placed on probation provided that as one of the conditions of his probation he pays the sum of $1,000 to the Treasurer of Hennepin County within two years.

The defendant Verhota, 38, 7501 Thirteenth Ave. S., Richfield, Minnesota, assistant manager of the same Minneapolis bar referred to above, who also entered his plea of guilty to the manslaughter charge on February 26, before being sentenced by Judge Hall admitted that he had a previous felony conviction in Hennepin County District Court on December 23, 1937, for using an automobile without the permission of the owner. He was then sentenced by Judge Hall to a term of not less than ten years nor more than twenty years at hard labor in the State Prison at Stillwater with the sentence being stayed for three years and the defendant placed on probation for the same period. Vernabell Tuma, 31, 3361 Xenwood Ave., St. Louis Park, Minnesota, employed in the same bar as a hostess, was sentenced to a term of not less than five years nor more than twenty years in the Women's Reformatory at Shakopee with the sentence being stayed for a period of three years during which time she was placed on probation by Judge Hall. Both Verhota and Tuma acted as intermediaries in arranging the abortion.

Mrs. Bellanger, who admitted she had performed a prior abortion in November, 1953, has no medical training or license to practice any form of healing in Minnesota. She did the abortion on January 30 in a Minneapolis hotel room by means of injecting a solution of soapy water and turpentine with a syringe. Peterson, who paid the $500 price for the abortion, turned the money over to Verhota and he kept $150 paying the balance to Tuma. She also retained $150 and paid $200 to Mrs. Bellanger. The young woman who submitted to the abortion was hospitalized subsequently in two Minneapolis hospitals but up until the time of her death she did not furnish the names of any of the defendants to the authorities, contending that the abortion was self-induced. Nevertheless, after her death an investigation disclosed that the facts and circumstances connected with the abortion were as related above.

Woman's Auxiliary

DOCTORS' WIVES URGED TO ATTEND DULUTH MEETING

A general invitation to all doctors' wives to attend the annual convention of the Woman's Auxiliary to the Minnesota State Medical Association, June 7, 8 and 9 in Duluth, has been issued by Mrs. C. H. Christensen, president of the St. Louis County Medical Society Auxiliary, hostess auxiliary for the meeting.

The convention is scheduled to coincide, as usual, with the 101st Annual Meeting of the doctors' organization and several important program events, such as the annual banquet and Open House, will be shared by both groups.

The women's program, arranged under the capable direction of Mrs. H. E. Bakkila, with the assistance of Mrs. I. T. Clark, both of Duluth, will begin with registration on Monday morning, June 7, at the Hotel Duluth. The pre-convention board meeting and luncheon will follow at the Kitchi Gammi Club. A tea, arranged through the courtesy of the Art Department of the University of Minnesota's Duluth Branch, will be a feature of Monday afternoon. It will be held from 3 to 5 p.m. at the Tweed Art Gallery, 2531 E. Seventh Street and it will be open to all visiting women. In the evening the women are invited to join their husbands at an Open House and entertainment to be staged in the Ballroom at the Hotel Duluth.

Tuesday's program begins with the annual business meeting and luncheon of the state Auxiliary which is scheduled for the Hotel Duluth. In the evening wives will be guests of their husbands at the annual banquet of the medical organization, also at the hotel. A "round-up" breakfast at the Duluth Women's Club Wednesday morning will bring the meeting to a close.

"Those who are already members of the Auxiliary know the state organization needs their support," Mrs. Christensen said in an appeal to all doctors' wives to attend the Duluth meeting and join in the Auxiliary's work.

"Like any organization, the Auxiliary is made up of individuals—which means you and me.

"We especially wish to urge all doctors' wives who are not already members to take this opportunity to acquaint themselves with the program of the Auxiliary. We feel quite sure they will find a spot in this program in which they would like to serve."

AUXILIARY CHAIRMAN REPORTS ON MEDICAL EDUCATION FUND

Some interesting and challenging figures, covering medical education in general and its relationship to the American scene, were provided in a report submitted recently by Mrs. J. A. Cosgriff of Olivia, Auxiliary chairman for the American Medical Education Foundation, for Minnesota.

There are seventy-nine medical schools in the United States whose function it is to train doctors to take care of a population of 158 million people, Mrs. Cosgriff points out in this report. These schools produce 6,500 doctors each year at a cost of $10,000 to $12,000 for each doctor. Tuition fees pay for about one-fifth of this amount. Taxes, donations, endowments must cover the rest. Only they failed by an estimated deficit of 19 million dollars, last year, to provide the amount required.

The trouble, according to the report, is that medical training is expensive. It takes 40 per cent of the total University budgets for only 10 per cent of the total number of students. And it is constantly growing more expensive as medical science advances. At the same time, endowments are dwindling, income from endowments has steadily decreased in purchasing power while costs have steadily risen. To complicate matters still further, the population has increased by more than 20 million since 1940 and is currently growing at the rate of 2,500,000 each year.

Alternatives Are Dangerous

The result for the seventy-nine accredited medical schools is obvious and inescapable. Unless new funds are made available most of them are faced with three equally dangerous alternatives. Either they must lower teaching standards or reduce the number of doctors graduated or accept subsidies from the federal government.

Government subsidy is patently dangerous, says Mrs. Cosgriff's report. To back up the statement she quotes President Eisenhower who said in a statement to Congress that the financial crisis facing medical schools "is a dangerous threat to the national welfare which must be met. The financial problems of medical schools should be solved through private rather than governmental means. Excessive reliance on the government violates the essential principle of our free-enterprise system." Clearly, such reliance could only invite federal domination of medical education.

Compromises in teaching standards, thus brought about, would soon be felt in every community. Local hospital services would deteriorate, family medical care would decline in quality and advances in medical research would be slowed and threatened.

Solution to the whole problem of medical school financing clearly rests upon a privately raised fund on a national level. The American Medical Education Foundation was established for this purpose in 1949, upon recommendation of the medical schools, the American Medical Association and representatives of industry, agriculture and labor. Three objectives were established. They were:

1. To make known the needs of medical education to the American people.

2. To raise annually from private sources the funds necessary to support the medical schools.

3. To distribute these funds equitably to the medical schools.

✦ Reports and Announcements ✦

THE AMERICAN SOCIETY OF MEDICAL TECHNOLOGISTS

The twenty-second annual National Convention of the American Society of Medical Technologists will be held at Miami Beach, Florida, June 13-17. The co-headquarters hotels are the Deland and DiLido.

CONFERENCE ON HEALTH IN COLLEGES

Forty national organizations interested in aspects of health and education are joining with the American College Health association in sponsoring the Fourth National Conference on Health in Colleges, May 5-8 in New York. They will consider ways of protecting and improving the health of college students. The theme is "Teamwork in Meeting the Health Needs of College Students."

The conference program will include sixteen working committees in which college and university presidents, deans, physicians, nurses, psychologists, specialists in physical educational and health education, student counselors, and students will pool their knowledge and experience to develop comprehensive health programs integrated with all other college functions.

Previous conferences were held in 1931, 1936 and 1947.

INDUSTRIAL HEALTH CONFERENCE

The 1954 Industrial Health Conference will be held at the Hotel Sherman, Chicago, Illinois, from April 24-30. The registration fee is $3.00. Reservations are to be made with the Industrial Health Conference Housing Bureau, Hotel Sherman.

April 26-30—Industrial Medical Association

April 25-27—American Conference of Government Industrial Hygienists

April 26-29—American Industrial Hygiene Association

April 27-29—American Association of Industrial Dentists

April 26-30—American Association of Industrial Nurses, Inc.

April 24-30—U. S. Navy I. H. Organization

EASTERN STATES HEALTH CONFERENCE

The 1954 Eastern States Health Education Conference of the New York Academy of Medicine will be held at the New York Academy of Medicine on Thursday and Friday, April 29 and 30. The program will include four sessions and an evening dinner meeting. The subject of this year's conference will be "Communication in Health Education." A workshop session will be held as part of the education conference and the concepts of communication will be applied to and tested in current health education materials and procedures.

Participation in the conference is limited. Those interested in the conference should mail their requests to Iago Galdston, M.D., The New York Academy of Medicine, 2 East 103 Street, New York 29, New York.

MEDICAL LIBRARY ASSOCIATION

The Medical Library Association will hold its fifty-third annual meeting June 15-18 in Washington, D. C. The headquarters will be the Hotel Statler, and the official host the Armed Forces Medical Library. The program will include a discussion on medical research by embassy attaches, tours of the National Institutes of Health, the National Naval Medical Center, and of the Armed Forces Medical Library. Delegates to the meeting will hear addresses by Dr. Detlev Bronk, President of the Rockefeller Institute of Medical Research, Lt. Col. Frank B. Rogers, Director of the Armed Forces Medical Library, Mr. Verner Clapp, the Acting Librarian of Congress, and Dr. Raymond Zwemer, Chief of the Library of Congress' Science Division. Further information can be obtained from Lt. Col. Frank B. Rogers, Armed Forces Medical Library, 7th Street and Independence Avenue S.W., Washington 25, D. C.

MINNESOTA SOCIETY OF NEUROLOGY AND PSYCHIATRY

A regular meeting of the Minnesota Society of Neurology and Psychiatry was held at the Town and Country Club in Saint Paul on March 9. The program consisted of "Clinical experience in the use of succinylcholine chloride (anectine) in electroshock therapy" by Dr. Burtrum Schield and Mr. Philip Margolis.

ALCOHOL PROBLEMS CONFERENCE AT UNIVERSITY APRIL 1-3

Drinking among young people and drinking and driving are two major topics which were considered at a University of Minnesota conference on the problems of alcohol April 1-3 at the University's Center for Continuation Study.

On the conference program were such outstanding authorities on the alcohol problem as Selden D. Bacon, director of the center of alcohol studies at Yale university; Dr. Paul Stevenson, psychiatrist of the National Institute of Mental Health, United States Public Health Service, Bethesda, Maryland, and the Rev. Forrest L. Richeson of Portland Avenue Christian church, Minneapolis.

The conference was planned by the University and the Minnesota Department of Health for physicians, nurses, welfare workers, judges, teachers, clergymen and other community leaders.

"Prime purpose of this conference," according to William F. Ferguson, chief of the section of mental health and consultant on alcoholism for the state health department, "was to mobilize communities to combat alcoholism. We hope the conference brought to light information about problems of alcohol in our society."

Bacon, a sociology professor who is considered the foremost authority on alcoholism, spoke on such subjects as "Drinking: Customs, Confusion and Conflict," "Nature and Extent of the Problem of Alcoholism," "Alcoholism—Therapy and Prevention" and "Mobilizing Community Resources to Combat Alcoholism." Bacon and an associate are the authors of the recently published book, "Drinking in College."

Stevenson's subjects were "Personality of the Problem Drinker" and "Alcoholism and the Family."

Rev. Richeson, who has personally counselled about 800 alcoholics in Minnesota, talked about a clergyman's contribution to an understanding of alcoholism.

HEART DISEASE COURSE AT UNIVERSITY

A course in cardiovascular diseases for general physicians was presented by the University of Minnesota and the Minnesota Heart Association March 22-24. In conjunction with the course, Dr. Samuel A. Levine, clinical professor of medicine, Harvard university, presented the annual George E. Fahr lecture. His topic was "Some Pitfalls in the Care of Cardiacs."

SCHERING AWARD SUBJECTS ANNOUNCED

To encourage scientific reporting and to stimulate medical students' interest in the ever expanding fields of therapy, the Schering Award Committee has announced the beginning of the ninth consecutive competition in 1954.

Titles of three subjects on which students in the United States and Canada are being invited to submit papers have been made known by George Babcock, Jr., M.D., chairman of the committee. They are:

(1) The Use of Androgen Therapy in the Female

(2) The Prophylactic and Therapeutic Uses of Parenteral Antihistamines

(3) Modern Treatment of Infections and Allergic Disorders of the Eye

For the best paper on each of these subjects, the committee will present one $500 first prize and a $250 second prize. Special citations and professionally useful gifts will also be awarded to all students who submit papers of merit. Outstanding medical authorities in each field will judge the papers.

Deadline for entry forms specifying the student's chosen title is July 1. All manuscripts must be mailed not later than October 1. Students may compete individually or co-operatively in research teams.

The purpose of the Schering Award is to encourage original reporting in the hope that students will later contribute to the essential communication of knowledge throughout the medical profession.

The Schering Award Committee will bring outstanding papers to the attention of editors of appropriate professional journals. Information and instructions for the competition are available from Schering Corporation, 2 Broad Street, Bloomfield, N. J.

ANATOMY BUILDING NOW JACKSON HALL

A University of Minnesota campus structure, known as the Anatomy building since it was erected forty-two years ago, has been redesignated Jackson Hall by order of the University's Regents. The hall was named for the late Dr. Clarence M. Jackson who became head of the division of anatomy in 1913 and lifted that department to a position of preeminence in the field of medical science.

Dr. Harold S. Diehl of the school of medical sciences announced the naming of Jackson Hall, April 1, at a dinner in the University's Campus club preceding the annual Clarence Jackson lecture. Dr. J. Garrott Allen, professor of surgery at the University of Chicago medical school, delivered the lecture, "Management of Upper Gastro-Intestinal Bleeding."

At the dinner, Elexious T. Bell, University professor emeritus of pathology, reviewed Dr. Jackson's service to the University.

Dr. Jackson, who died at the age of seventy-one on January 17, 1947, gained recognition as one of the first medical school leaders to launch a modern research department. He was acting dean of the graduate school in 1917-18 and again in 1925. He retired in 1941.

Dr. Jackson was editor of Morris Human Anatomy, a widely used textbook, and head of the medical division of National Research Council in Washington, D.C., in 1923-24.

WOMAN'S AUXILIARY

(Continued from Page 312)

The AMEF got off to a slow start but now shows forty-one out of the forty-eight states making substantial contributions to the fund.

The Woman's Auxiliary to the American Medical Association contributed $100,000 from its treasury, and individual state and county auxiliaries gave more than $22,000 in 1953.

1954 Contributions Requested

"We auxiliary members have pledged ourselves to help in this most worthy cause," Mrs. Cosgriff reminds the women in this report. "Let us redouble our efforts this year.

"We are still hoping," she says, "that every county auxiliary in the State of Minnesota will make a voluntary contribution to the fund before the year 1954 ends. Earmark your contribution. That is, make a notation on your check indicating whether you wish it to be used for the University of Minnesota, specifically, or if you wish it merely to be added to the general fund. Send it to the treasurer of the State Auxiliary, Mrs. Charles W. Froats, 1406 Edgcumbe Road, Saint Paul, Minnesota."

In that connection, Mrs. Cosgriff notes that "In Memoriam" cards are still available to members, and may be obtained from the state AMEF chairman.

In Memoriam

WILFRED P. FRELIGH

Dr. Wilfred P. Freligh, Albert Lea surgeon, died after a brief illness at St. Mary's Hospital in Rochester, February 28, 1954. He was sixty-six years old and had practiced at Albert Lea for the past thirty-four years.

Dr. Freligh was taken ill while he was vacationing in Phoenix, Arizona. He was flown back to Rochester with his wife the day before he died.

He was born in Stillwater and went to school there and at the University of Minnesota, where he received a B.A. degree in 1911 and his medical degree in 1913. He served internships at Abbott Hospital in Minneapolis and at Ancker Hospital in St. Paul. A fellowship followed at the Mayo Clinic in the course of which, he was Dr. Charles H. Mayo's assistant for three and one-half years.

In 1922 Dr. Freligh established himself in Albert Lea and became a member of the staff of the Naeve Hospital of which he was a past-president. He was a lieutenant in the U. S. Army Medical Corps during World War I and was active during his entire career in city, county and state medical groups. He was a member of the Freeborn County Medical Society which he served in a number of official capacities, the Minnesota State Medical Association and the American Medical Association. He was a member, also, of the Alumni Association of the Mayo Clinic, a warden of Christ Episcopal Church of Albert Lea, a past commander of Leo Carey Post of the American Legion, a past director of the Albert Lea Chamber of Commerce, a member of the Elks, of the YMCA and of the Country Club.

Surviving are his wife, the former Irene V. Comstock, and one son, Robert John, 17; also a sister, Mrs. Everett Doran, Sr., of Los Angeles, and a brother, Harold, of Omaha, Nebraska.

GERALD ARTHUR KNUTSON

Dr. Gerald A. Knutson, well-known Northern Minnesota physician, died suddenly as the result of an embolism, at his home in Hallock, Sunday, March 3, 1954. He was forty-eight years of age.

Death came as the probable consequence of an automobile accident which occured a week earlier as he and his wife were returning to Hallock from Grand Forks where he had gone for a physical examination at a clinic there. Mrs. Knutson suffered several injuries, including probable loss of an eye, and was hospitalized at the time of Dr. Knutson's death. Dr. Knutson, himself, had apparently escaped serious injury and was preparing to go to his office when he was stricken.

He was born at Buxton, North Dakota, the son of Dr. O. A. Knutson, a physician, there, and Mrs. Knutson. He attended the Buxton schools and the University of North Dakota from which he was graduated with B.A. and B.S. degrees. He received his degree in medicine from Northwestern University and served his internship at Ancker Hospital in St. Paul. He practiced medicine in Greenbush for eight years until a fire wiped out his hospital, home and office there. After that he applied for a commission in the Navy and served for three and one-half years during World War II. He held the commission of lieutenant in the Navy when he was discharged and shortly afterwards he went to Hallock to take over the practice of the late Dr. A. W. Shaleen.

Dr. Knutson was widely known in Northern Minnesota. He had recently accepted an appointment to the local board of health of Hallock and he was a member of the Lutheran Church there. He was also a member of the Red River Valley Medical Society, the Minnesota State Medical Association and the American Medical Association.

Surviving are his wife, the former Rush Aaseby, and five children including Carol, now a student at the University of Minnesota, Gerald and Aileen, high school age, Cynthia, a Hallock grade school student, and Richard, below school age. His parents, Dr. and Mrs. Knutson of Buxton survive him, also a brother, Dr. George Knutson, a physician of Negaunee, Michigan, and one sister, Mrs. G. L. Hanson of Mount Vernon, Washington.

FRED HARWOOD POWERS

Dr. Fred Harwood Powers, Rochester physician for many years, died February 27, 1954, at St. Mary's Hospital in Rochester after a long illness.

Dr. Powers was born in Bloomington, Illinois. He attended high school at Shelbyville, Illinois, and graduated in 1890 from the University of Illinois College of Pharmacy. Later he attended Rush Medical College in Chicago and received his medical degree there in 1900.

He practiced for some years in Illinois, Wisconsin and Ohio and then established himself in general practice, twenty-eight years ago, at 301½ South Broadway in Rochester. He was a member of the Olmsted-Houston-Fillmore-Dodge County Medical Society, the Minnesota State Medical Association and the American Medical Association. He became a life member of the State Association in 1952.

At one time, Dr. Powers operated a small, private hospital in Rochester. He was on the examining board for the air forces, also. He was a 32nd degree Mason, a member of the Order of the Eastern Star, the White Shrine and AOUW.

Surviving are his wife, the former Cora Sprecher, and three daughters, Mrs. Margaret Parish, Chicago; Mrs. George T. Mellinger, New Orleans, Louisiana; and Mrs. Grant H. Elford, Audubon, Iowa. There are five grandchildren.

Of General Interest

Establishment of an outpatient psychiatric clinic for adults in Saint Paul with **Dr. Clarence J. Rowe** as director of the clinic, has been announced.

The psychiatric center will provide free or part-pay treatment of the mental and emotional ills of persons who are unable to pay the cost of private psychiatric service.

The clinic will accept only patients who are referred to it by physicians, public health agencies, other outpatient clinics, the courts and social agencies.

Recommendation for the establishing of such an outpatient psychiatric clinic for adults came from a committee of doctors, social workers and lay people appointed in June, 1952, by the Saint Paul Area Public Health Council. This committee, headed by Mrs. John Driscoll, made a study of the need for psychiatric services for those persons who are unable to pay the cost of private psychiatric treatment.

The committee report and the establishment of a clinic were approved by the Public Health Council, the practicing psychiatrists in Saint Paul, the executive committee of the Ramsey County Medical Society and the planning and research council of the Saint Paul Community Chest and council.

Location of the clinic has not yet been definitely determined, but it will probably be in a downtown office building. It is hoped that operation can begin about July 1, when Dr. Rowe's appointment takes effect.

Dr. Rowe will head a professional staff that will include a clinical psychologist and three psychiatric social workers. He has been on the staff of the University of Minnesota School of Medicine since 1949, and is an assistant professor in the department of psychiatry and neurology. He has also been attending psychiatrist to the Veterans Administration Hospital for three years and psychiatric consultant for the Family Service of Saint Paul. He is a member of the American Psychiatric Association and the Minnesota Society of Neurology and Psychiatry as well as a diplomate of the American Board of Psychiatry and Neurology.

* * *

Dr. George N. Kraemer, formerly of Mankato, has joined the staff of the Thayer-Wandke clinic. Dr. Kraemer is a graduate of the University of Minnesota, a veteran of World War II, and a resident in surgery at Minneapolis General Hospital from 1949-1953.

* * *

Dr. Allen Hodges, Albert Lea, and **Dr. Tracy Barber,** Austin, discussed the functions of a mental health clinic and problems in mental health at Neveln PTA in Austin.

Dr. J. J. Heimark, Fairmont physician who has practiced in Tri-Mont the past year and a half, is returning to Fairmont to resume his practice in his former office there.

* * *

Dr. Frances E. Schaar recently opened her office at sixty-seventh and Lyndale as a pediatrician. She has been with the University hospital since 1947, and is a graduate of the University of Illinois medical school.

* * *

Doctors C. G. Wingquist and **A. R. Anderson** have moved into their newly completed office building in Crosby. The one-story structure houses nine rooms on the left of the building and five-room dental office on the right. The exterior has stuccoed sides and a brick front. The lots on either side of the building will provide parking areas for patients.

* * *

Dr. A. I. Arneson, Morris, was the speaker for the Father-Son Banquet at the Glenwood Lutheran Church on February 15. Dr. Arneson has made a number of expeditions out of the States hunting big game and he showed one of his motion pictures taken while hunting in British Columbia.

* * *

Dr. Theodore Bratrud, Thief River Falls, started his new duties on the staff of the department of pathology, March 1. He will complete his work for a Ph.D. degree in pathology.

* * *

Dr. F. H. Baumgartner, Albany, was honored at a testimonial dinner for his ten years of faithful service as mayor of Albany. **Dr. J. B. Beuning,** former Albany physician and surgeon, was the principal speaker.

* * *

Dr. W. F. Maertz, formerly of Saint Paul, has been appointed to the staff of the Anoka State Hospital.

* * *

Dr. Harry M. Weber, Rochester, was among eighteen on a guest faculty that assisted in the annual postgraduate course in radiology at the University of Kansas medical center in Kansas City in February.

* * *

Dr. J. K. Butler, Cloquet, was elected to the executive committee of St. Mary's hospital, Duluth, at their annual staff meeting held on February 4. Dr. Butler will be chief of the department of general medicine at St. Mary's.

* * *

Dr. Andrew V. Grinley, Grand Rapids, was elected chief of staff at Itasaca Memorial hospital in February.

* * *

Dr. and Mrs. C. J. Olson, Belle Plaine, left February 1 for Temple, Texas, where he took a two-week postgraduate course in heart disease at the Scott Sherwood-Brindley Foundation of the University of Texas Medical School.

* * *

Lt. Donald S. Amatuzio, formerly of Duluth, now serving with the U. S. Navy in Japan, recently participated in a unique joint meeting of United States Medical Officers and the Yokosuka and Miura Medical society. Lt. Amatuzio spoke at the meeting attended by 50 Japanese and 100 American doctors. As part of a technical session, Lt. Amatuzio discussed the rapid intravenous dextrose tolerance test. He is a specialist in internal medicine.

* * *

Dr. C. W. Moberg, Detroit Lakes, was guest speaker at the February meeting of the Business and Professional Women's Club. His topic was rheumatic fever.

* * *

Dr. Ralph E. Smith, Department of Medicine at the Veterans and University Hospitals, Minneapolis, was the guest consultant discussing valvular heart disease at the monthly staff meeting of the Litchfield Hospital.

* * *

Dr. Beryl Kennedy of the University of Minnesota Hospital staff meet with the Meeker County Hospital Medical staff at their monthly meeting on March 2. Dr. Kennedy discussed breast cancer with special emphasis on the effect of the use of hormones in its treatment. The clinical conference program throughout Minnesota is sponsored by the Minnesota Department of Health, Minnesota Medical Association, University of Minnesota, Minnesota Heart Association, and the Minnesota Cancer Society.

Volunteer leaders of the American Cancer Society's Minnesota Division, met on February 10 and 11 in Minneapolis. They planned an expanded program of cancer control, education and service. **Dr. Bernard Zimmerman**, Cancer Co-ordinator, University of Minnesota, headed a round-table discussion "The Cancer Problem." Participating in this panel were: **Dr. Marthella J. Frantz, Dr. F. John Lewis, Dr. Donn Mosser,** and **Dr. B. J. Kennedy,** all of the University School of Medicine.

* * *

Dr. Marguerite Schwyzer, Saint Paul, suffered a fractured leg in an accident north of Pine City. En route to Miller Hospital, in an ambulance, February 22, they were involved in another collision on Ninth and Main streets in Saint Paul.

* * *

Dr. Robert L. Pedersen, who has been associated with **Dr. W. E. Macklin** in the X-ray and radiology department at the Rice Memorial Hospital, Willmar, left for Brainerd, where he will head a similar department at the hospital there.

* * *

Dr. Frank H. Krusen, chief of the section on physical medicine, Mayo Clinic, received the President's award for 1953 at Louisville, Kentucky, February 24, during the American Medical association's fourteenth annual Congress on Industrial Health. The award is conferred annually for outstanding contributions to the employment welfare of the handicapped. Dr. Krusen is chairman of the AMA council on physical medicine and rehabilitation.

* * *

Dr. Martin O. Wallace, Duluth, spoke at the Duluth Health service annual luncheon meeting on February 25. His subject was "The present status of health insurance plans."

* * *

Dr. M. Smorazczok, Monticello, spoke to the PTA in Annandale on February 15. Dr. Smorazczok is a native of Poland; he spent two years in a concentration camp. He spoke on various phases of government under the Communist rule, schools, religion, freedom and other points.

* * *

William R. Merifield will be associated with **Dr. Marvin J. Geib**, Moorhead, in his practice of psychiatry as Clinical Psychologist. Mr. Merifield is a graduate of the College of William and Mary with a major in Clinical Psychology. His internship was completed in the Neuro-psychiatric service at Fort Lawton, Washington.

* * *

Dr. E. J. Engberg, of the Minnesota School and Colony, Faribault, has satisfied the standards set up by the Advisory Board for Medical Specialties for inclusion in the current edition of the Directory of Medical Specialists. Dr. Engberg has qualified as a specialist in the field of psychiatry and neurology.

* * *

Dr. and Mrs. H. L. Stemsrud, Alexandria, left February 26 for a ten-day trip to visit relatives in Milwaukee and to attend a medical conference at the Palmer House in Chicago.

* * *

Dr. J. L. Delmore, Sr., Roseau, was honored with a membership card in the Minnesota Medical Association in the form of an inscribed gold plate in recognition of his 40 years of service in the medical profession.

* * *

Dr. Paul G. Bauer has opened an office for the general practice of medicine in Faribault. A graduate of the University of Minnesota School of Medicine, Dr. Bauer took his internship at St. Barnabas Hospital. He served in the Army for three years. His tour of duty included 18 months in Korea as a regimental surgeon.

* * *

Duluth physicians have accepted a goal of $200,000.00 for themselves in the $1,250,000 St. Mary's Hospital Building Fund campaign. **Dr. R. P. Buckley**, chairman of the medical division, made the announcement at the sponsor's committee dinner, February 16. He said Duluth physicians had determined the size of their objective themselves, and had approved it. Teams of doctors will solicit fellow-practitioners in an effort to reach or surpass the goal.

The Renville County Hospital at Olivia commemorated its third anniversary on February 5. In the period since its opening, the hospital has served 5,356 men, women, and children as in-patients admitted, as well as 1,238 people treated as out-patients. During the same period, 1,725 surgical operations have been done in the hospital and 931 babies have been born. **Dr. J. A. Cosgriff**, Olivia, expressed thanks to the members of the Hospital auxiliary for the service they have rendered to the hospital.

* * *

Dr. H. P. Van Cleve, Austin, addressed the Whittier PTA on February 16. He discussed the need for a mental health clinic and the purposes of a family counseling service.

* * *

Dr. Martin O. Wallace, Duluth, was the principal speaker at the Duluth Health service's annual dinner. He warned against health plans of too extensive a nature. Dr. Wallace asserted that in England where compulsory plans are extensive abuses have led to lower quality of medical service. "Voluntary, rather than compulsory insurance is cheaper in the long run and maintains a better doctor-patient relationship," Dr. Wallace said.

* * *

Open house was held February 20 in the new clinic building which was opened by **Dr. W. J. Alcorn** in Wabasso. The building includes a waiting room, a room for administration of various types of treatment, the doctor's private and main office, two examining rooms, a pediatric room for care of infants, x-ray room, laboratory room and darkroom. The structure is 31 feet wide and 45 feet long. Construction was begun last summer.

* * *

Dr. W. D. Cleaves, Sauk Centre, has moved into new offices in his recently constructed building on Third street.

* * *

Dr. Tracy Barber, Austin, was elected president of the Austin YMCA at the kickoff banquet for the 1954 membership enrollment campaign February 17. Dr. Barber is a charter member of the YMCA and a past president of the board of directors. He has been medical director of the George A. Hormel Company since 1948.

* * *

Problems of investigating violent deaths were discussed at the University of Minnesota's coroners' conference March 8. **Dr. Walter Jetter**, professor of legal medicine of Boston university school of medicine, spoke on poisonings, deaths in conflagrations and drownings and suspected drownings. Milton Helpern, assistant professor of forensic medicine, New York university, discussed stabbings and rape, and Briggs J. White of the Federal Bureau of Investigations talked about "trace evidence" and facilities of FBI laboratories.

* * *

Dr. Richard A. Groat, a cosultant in the section on anatomy and associate professor of anatomy in the Mayo Foundation, has resigned from the staff of the Mayo Clinic to begin an internship at City Memorial hospital, Winston-Salem, North Carolina.

* * *

Four Mayo Clinic surgeons participated in the scientific program of a sectional meeting of the American College of Surgeons at Omaha, Nebraska, on March 1-4. **Dr. Thomas H. Seldon** took part in a symposium on trauma; **Dr. Frederick A. Figi** participated in a discussion of cancers of the head and neck; **Dr. O. T. Clagett** took part in a symposium on esophagogastric junction; and **Dr. Howard K. Gray** discussed lesions of the pancreas.

* * *

Dr. Robert B. Pierce is dividing his time in the practice of medicine between Renville and Olivia.

* * *

Dr. Byrl Kennedy, Assistant Professor of Medicine, University of Minnesota, spoke at the first of four clinical conferences for the McLeod County Medical Society in Glencoe on February 25. He discussed new drugs in cancer treatment.

* * *

Dr. Joseph S. Collins, Wabasha, is completing his fiftieth year as a physician and surgeon and was made a life member of the Minnesota State Medical Association and the Wabasha County Medical Society.

* * *

Drs. R. P. Griffin and **N. W. Wagner**, Benson, announced the formation of a partnership which went into effect March 1. Dr. Griffin, a navy veteran, has been in practice in Benson for seven years. Dr. Wagner became associated with Dr. Griffin about five months ago; previously he had been in Graceville.

* * *

Dr. and Mrs. C. F. Cervenka, North Branch, recently attended the Chicago Medical Society's annual clinical conference which was held at the Palmer House from March 2 to 5.

* * *

Dr. Robert Gray, Marshall, recently spoke to the Marshall chapter of the University Women at their monthly meeting. He spoke of his experiences in Africa where he spent several years as a physician with the British and American armies and of his findings when he returned later under a Fullbright Scholarship to study native medicines. He told of the problems, politically and socially, that face Africa and those endeavoring to educate and civilize the many tribes there.

* * *

Dr. Donald E. Dille, Litchfield, attended the University of Minnesota coroners' conference March 8-10.

The process of incorporating to bring a medical center to Hawley began early in February. Shares of stock are to be sold for $100. Committees have been appointed to inspect various medical centers.

* * *

Dr. Paul Winchell was the guest consultant at the first of two clinical conferences for the medical staff at the Montevideo Hospital on March 8. Dr. Winchell of the Department of Medicine at the Heart Hospital on the University Campus discussed case histories on heart disease, particularly emphasizing the types of cardiac diseases that are suitable for heart surgery.

* * *

Dr. Gaylord Anderson, director of the school of public health at the University of Minnesota, spoke to the annual mid-winter meeting of the Women's Auxiliary to the Minnesota State Medical association at the International Institute. He discussed the new polio vaccine and gave general information on the work of the physician and how doctors' wives fit into the picture.

* * *

Dr. Julian S. Ansell, medical fellow at University hospitals and Veterans hospital, and **Dr. Frank MacDonald,** staff physician at the Veterans Hospital, were guest speakers at a one-day private duty institute of the Minnesota Nurses association February 18 and 19.

* * *

Dr. John Tobin, pediatrician, took part in a panel discussion for parents at St. George's Episcopal Church in St. Louis Park.

* * *

Mr. and Mrs. Ivan H. Roberts, Judson, announce the engagement of their daughter, Gloria, to **Dr. Frank J. Carthey,** New Ulm. Dr. Carthey is a graduate of the School of Medicine and the University of Minnesota and is now associated with the Seifert Clinic of New Ulm.

* * *

Dr. Ivan G. Baronofsky, assistant professor of surgery at the University of Minnesota, discussed "Research in the Heart Field" at a luncheon meeting of the Exchange club in Saint Paul on February 2.

* * *

Dr. Robert G. Tinkham, Minneapolis, was elected vice chairman of St. Barnabas hospital medical staff in February.

* * *

Dr. Andrew V. Grinley, Grand Rapids was elected chief of staff at Itasca Memorial Staff in February. **Dr. John Evensta** of Grand Rapids will be assistant chief, and **Dr. R. T. Kelly** of Nashwauk was named secretary. Members of the executive committee for the medical staff are **Dr. O. C. Braun, Dr. Gordon M. Erskine** and **Dr. M. J. Schirber.**

* * *

Dr. J. K. Butler, Cloquet, was elected to the executive committee of St. Mary's hospital, Duluth, at their annual meeting held on February 4. Dr. Butler will be chief of the department of general medicine at St. Mary's.

A conference on sterility and associated problems of reproduction in the human race was presented for physicians at the University of Minnesota center for continuation study in February. Dr. Alan F. Guttmacher, director of the department of obstetrics and gynecology, New York City, and a clinical professor at Columbia, was the guest speaker.

* * *

Dr. Edward Allen Boyden, head of the anatomy department in the University of Minnesota medical school, received a special tribute from his friends and associates in observance of his sixty-eighth birthday March 20.

The tribute was the "Boyden Birthday Volume" of *The Anatomical Record,* scientific monthly journal published for anatomists. The special volume consist of four issues of the publication, January through April, 1954. Dr. Boyden, who has been a professor of anatomy at the University since 1931, served as managing editor of the journal for 20 years, 1928-48.

The January issue consists of a short biography of Dr. Boyden, a list of his many publications and five scientific papers contributed by eleven of his colleagues in the anatomy department. Additional papers by former associates will appear in the February, March and April issues.

Dr. Boyden received most of his training at Harvard university where he earned his doctor of philosophy degree in the medical sciences in 1916. He also studied medical anatomy for a year at the University of Freiburg, Germany. He has served on the staffs of six American universities: Harvard, Stanford, the University of California, the University of Illinois, the University of Alabama and the University of Minnesota. His publications include three books, 111 articles in scientific journals and some fifty abstracts and book reviews.

The Minnesota anatomist's studies of the kidneys, gallbladder and lungs have brought him international fame. According to one of his associates, he has made a greater number of important contributions to knowledge of the structure and functioning of the gallbladder and related tubes than any other investigator.

In 1925, he published the first x-ray picture of the normal contraction of the gallbladder in response to a meal of egg yolk. The "Boyden meal" of egg yolk is still a standard test for biliary disease.

During the last eight years, Dr. Boyden has made an intensive study of the segmental anatomy of the lungs. His observations are considered invaluable to the surgeon who wishes to remove a small, diseased part of one lobe of a lung.

His contributions in the field of x-ray diagnosis of gallbladder and lung diseases are the most important of those of any living anatomist—in the judgment of a colleague in the University medical school.

"Through the years, Dr. Boyden has brought illumination to every subject he has investigated," Dr. Charles H. Danforth, professor emeritus of anatomy, Stanford university, asserted today. "He has been, and continues to be, a potent influence in shaping the quality and the direction of the science of anatomy in America."

* * *

Dr. Walter Judd was the principal speaker at a Ninth District Lincoln Day dinner attended by well over 200 people in Warren. **Dr. Ch. H. Holmstrom,** Warren, served as toastmaster.

* * *

Dr. Ch. H. Holmstrom, Chairman of the Warren School Board, spoke at the opening of Warren's new gymnasium.

A substantial increase in patients treated at Warren hospital has been noted. Last year a total of 1,842 patients were admitted as compared to 1,603 in 1952, 1,736 in 1951 and 1,697 in 1950. Total number of patient days increased from 8,507 in 1952 to 9,675 last year. The daily average was 26.5 patients.

* * *

Dr. Donald Steward, Northwestern Clinic, Crookston, spoke to the members of the Rosseau County Medical Society at the home of **Dr. and Mrs. Lloyd Klefsted,** Greenbush. Dr. Steward spoke on "Bowel obstruction." Several types of tubes for intubation were shown and demonstrated as well as x-rays of actual cases.

* * *

Dr. O. M. Geilberg is the new president of the medical staff of the Worthington Municipal hospital. He was named at the annual election meeting of the group held recently. Other officers named include **Dr. D. J. Halpern,** Brewster, vice president, and **Dr. F. L. Shade,** secretary.

* * *

Dr. W. F. Skaifé was elected chairman at the recent annual meeting of the Nursing Advisory Board, Little Falls. The board is aiding the nursing service to compile a list of women in the county who are willing to help care for children or old people when assistance is needed.

* * *

Dr. John F. Kane, who has been associated with the Hartfiel Medical Center, is leaving Montevideo to become chief surgeon at the Veterans Administration hospital in Miles City, Montana. **Dr. George Martin** and **Dr. J. J. Carroll** who have also severed their connection with the Hartfiel Center are completing arrangements for practice in other cities.

* * *

Officers were elected at the annual meeting of the Upper Mississippi Medical association in Brainerd. Ten counties were represented by 53 doctors. The new officers include **Dr. C. W. Vandersluis,** Bemidji, president; **Dr. V. E. Quanstrom,** Brainerd, first vice-president; **Dr. Luther Davis,** Wadena, second vice president; **Dr. W. Parker, Sebeka,** third vice president; **Dr. G. I. Badeaux,** Brainerd, secretary. Chosen as delegates to the state society were **Dr. Luther Davis,** Wadena, and **Dr. A. M. Watson,** Royalton. Alternates are **Dr. William Anderson,** Brainerd, and **Dr. Douglas Johnson,** Little Falls.

Failure to report several cases of less serious communicable diseases has resulted in a very healthy appearing annual health report for the city of Fairmont, **Dr. M. H. Marker,** city health officer, said as he turned over his report to the city council at its February meeting. The report shows that the city had three cases of polio, two of typhoid fever, one of tuberculosis and one of scarlet fever.

* * *

Quarrelling in children is not all bad, **Dr. Robert Faucett,** psychiatrist and a member of the Mayo Clinic staff, told members of the parents group of the Aldrich Memorial Nursery school. He said that there are some good and constructive things about sibling rivalry in that it can teach a child how to get along in a competitive world. Dr. Faucett was moderator for a panel discussion on "Sibling Rivalry and Jealousy in Children." Also taking part was **Dr. H. F. Helmholz, Sr.,** emeritus member of the Mayo Clinic staff in the pediatrics section; he pointed out the importance of trying to see a situation from a child's point of view and emphasized that parents must avoid making children jealous by comparing their accomplishments with others.

* * *

Dr. and Mrs. H. J. Elliott of the Hayfield Medical Center showed slides of their work as medical missionaries in Africa at a meeting of the Kasson PTA in February.

* * *

Dr. Grace Roth of the Mayo Clinic and associate professor in physiology of the Mayo foundation spoke on "You and Your Heart" at a dessert meeting of the Scandinavian club February 22 at the YMCA in Rochester.

* * *

A plan which would make cancer tests available to everyone in Minnesota was explained by **Dr. David P. Anderson,** Austin, president of the Minnesota Cancer Society, at a meeting of the volunteer cancer workers. In his speech Dr. Anderson said that under the program sponsored by the Minnesota State Medical Association, doctor's offices would be made cancer detection centers. Patients would undergo the tests designed to detect cancer before any symptoms appear, as a part of their yearly physical examinations.

* * *

The Medical Staff of the Lutheran Hospital held its business meeting February 17. The following officers were elected: **Dr. Harry Palmer,** Blackduck, president; **Dr. John Griffin,** vice president, and **Dr. D. D. Whittemore,** secretary-treasurer.

* * *

Dr. L. R. Gowan spoke to the St. Mary's Council on Volunteers, Duluth, on the subject "Psychiatry in the general hospital."

* * *

Two University of Minnesota surgeons and a former member of the University medical school pediatrics staff have been awarded grants of $30,000 each by the John and Mary R. Markle Foundation of New York which has named them "Scholars in Medical Science." Announcement of the awards was made by John M. Russell, executive director of the foundation.

The Minnesota scholarship winners are: **Dr. Gilbert S. Campbell,** 829 25th Avenue S.E., Minneapolis, resident in surgery, and **Dr. Mitchell W. Spellman,** 2021 Commonwealth Avenue, Saint Paul, assistant professor of surgery and research fellow. Both are on the staff of Dr. Owen H. Wangensten, University surgery chief.

Also named a Markle scholar was **Dr. Robert A. Ulstrom** who left the University's pediatrics department staff last September to become an assistant professor of pediatrics at the University of California school of medicine, Los Angeles.

The Markle grants are being awarded this year to twenty-five faculty members of medical schools in the United States and Canada. Each grant is awarded at the rate of $6,000 annually for five years, according to Russell, "to offer both academic security and financial help to faculty members at the start of their careers in academic medicine. They (the twenty-five) were selected from sixty candidates nominated for the grants by deans of medical schools."

Four other University of Minnesota doctors received the scholarships in previous years. They are **Dr. George E. Moore,** 1949, then instructor in surgery and now director of Roswell Park Memorial Cancer institute at Buffalo, N. Y.; **Dr. Robert A. Good,** 1950, associate professor of pediatrics; **Dr. Leonard F. Peltier,** 1952, assistant professor of orthopedic surgery; and **Dr. William F. Scherer,** 1953, assistant professor of bacteriology.

* * *

BLUE SHIELD-BLUE CROSS NEWS

Of increasing interest is the statistical data compiled annually which shows the utilization of Blue Shield and the number of services furnished Blue Shield subscribers by doctors of medicine. On a comparative basis, each type of service in 1953 increased numerically over the number in 1952 and the dollar payment for each service also showed an increase. Such services as in-hospital medical care, emergency medical care, obstetrical, surgical and ancillary services show a marked increase both in the number of cases in 1953 over 1952, and in the amount paid by Blue Shield for each of such services to doctors of medicine.

During the year 1952, the average payment made to doctors for in-hospital medical care was $22.80 per case. In the year 1953, this amount increased to $24.66 per service while the number of such cases increased 13 per cent over 1952. More remarkable is the increase in emergency medical care payments, and the increase in the number of such cases compared with the year 1952. Payments during the year 1952 for emergency medical care average $31.01 per case. However, in the year, 1953, this payment increased to $38.38 per case or an increase of $7.37 more than the amount paid per case in 1952. In addition, the number of such cases of this nature almost doubled.

Obstetrical services furnished Blue Shield subscribers have always been one of the more frequent of Blue Shield services, and while the cost per case in 1953 was approximately the same as the cost in 1952, the number of such cases increased 8.5 per cent over 1952. The cost per case shows the amount paid by Blue Shield to be greater than the scheduled allowance for a normal delivery, but this is clarified by the fact that included in the figures are the higher benefits for cesarean deliveries. This increased cost of obstetrical cases will further increase in 1954 since the Blue Shield allowance for routine obstetrical deliveries has been raised from $50 to $60.

While surgical services rendered Blue Shield subscribers showed an increase of 14 per cent over the number in 1952, the average service payment in 1953 remained practically the same as that of 1952.

Another classification showing marked increases are those known as ancillary services. These include anesthesia, x-ray and endoscopic services. Each increased over 1952. Anesthesia cases, for example, increased in number 31.6 per cent over 1952 and the cost of anesthesia services was 33 per cent greater than in 1952. X-ray services increased in number and the cost increased correspondingly. A greater increase was noted in the number of endoscopic services which amounted to 26 per cent above that of 1952, and the cost of endoscopic services was slightly greater per case in 1953 than in 1952.

It is apparent from these analyses that in both the number of services and the amounts paid for the different services, Blue Shield service to subscribers and doctors has grown appreciably in 1953 as compared with 1952. With the increase of fees or benefits which became effective for services rendered on and after January 1, 1954, there is a great likelihood that the increases in both volume and costs will be even greater in 1954.

Blue Cross subscribers and their dependents used more hospital care in 1953 than in any year in the history of Minnesota Blue Cross. A total of 167,484 participant subscribers . . . one out of every six . . . were hospitalized and over fifteen million dollars was provided for their care, an increase of approximately 2½ million dollars over 1952.

The record breaking number of hospital cases paid during the year (1953) represented an increase of 14 cases per year per 1,000 contracts protected over the previous year.

This increase, it was reported, occurred in the number of bed-patient cases . . . 144,006 participant subscribers received bed-patient care during 1953 compared with 142,372 participant subscribers in 1952. The average length of hospital stay for bed-patient care during 1953 was 6.5 days compared with 6.2 days in 1952.

Out-patient care during the year was given to 23,478 participant subscribers compared with 24,673 during 1952. This increase in bed-patient care and decrease in out-patient services resulted in an increase in the

(Continued on Page 322)

BOOK REVIEWS

Books listed here become the property of the Ramsey, Hennepin and St. Louis County Medical Libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

THE ANATOMY AND SURGERY OF HERNIA.

By Leo M. Zimmerman and Barry J. Anson. 350 pages. Illus. Price $10.00. Baltimore: Williams and Wilkins, 1953.

This new publication dealing with various types of hernia places major emphasis on the inguinal hernia. However, it deals with all types of hernia, and the discussion of each is thoroughly satisfactory. The anatomical section is thorough and meticulously carried out. The section on surgical technique covers diagnosis, preoperative preparation, choice of anaesthetic and detailed description of surgical technique. The authors' ideas in dealing with hernia differ somewhat from the accepted concepts; however, their ideas are good and are well founded. The book loses a great deal of its effectiveness because of needless repetition. The reader is belabored with details of anatomy which are presented adequately in other parts of the book.

The book is a worthwhile addition to the general surgical library.

T. M. Owens, Jr.

PLANNING GUIDE FOR RADIOLOGIC INSTALLATIONS.

By Wendell G. Scott, M.D., chairman of the committee on planning of radiologic installations of the commission on public relations of the American College of Radiology. 336 pages. Illus. Price $8.00. Chicago: The Year Book Publishers, Inc., 1953.

With the marked advances of x-ray in the fields of diagnoses and therapy, the radiologist and his associates have found a place of increased importance in the field of clinical medicine. Slowly, but inevitably, the x-ray department has emerged from its few dusty rooms in the basement to become the very center of the community hospital. Because of the broad use to which x-ray has been put and because of its extensive diagnostic and therapeutic contributions, the department of radiology has become the meeting place for physicians in the hospital; a place for them to congregate and discuss their cases with the radiologist and other colleagues. Planning and innovations in the design of radiologic installations have not kept pace with the rapid growth of this specialty. In certain geographic areas there is evidence of originality of design in the functional arrangement of the departments, but these are few and, only too frequently, the radiologist has had no part in the planning and arrangement of a department of which he is to assume direction.

In this authoritative guide, the viewpoints of radiologists, physicists, architects and hospital administrators have been assembled into one exhaustive manual for the first time. Consideration has been given to every type of installation, from a small office to a large hospital department. Adequate space is devoted to diagrams and ideas for the flow of all activities in the radiology department so as to achieve "the most effective traffic pattern for the radiologist and professional staff so that they may interview, examine and treat patients as quickly and thoroughly as possible." Of marked importance are the data for adequate protection of a radiological installation for the radiation worker as well as anyone working in adjacent areas.

This book is invaluable to those persons responsible for the installation of any type of x-ray equipment, be he a general practitioner, a dentist with a single x-ray unit or the director of a large x-ray department.

J. F.

BIBLIOGRAPHY OF OCCUPATIONAL HEALTH.

Public Health Service Publication No. 300. Washington, D. C.: Government Printing Office, 1954.

A comprehensive bibliography of Public Health Service publications on occupational health subjects issued through 1953 has just been released by the U. S. Public Health Service.

The purpose of this bibliography is to provide a complete and continuing record for reference use. It calls to the attention of the readers, particularly those new to occupational health, voluminous information on early pioneering studies and other contributions by the Public Health Service to the detection and control of occupational diseases. At the same time, by reflecting changes in subject matter from year to year, it affords a historical perspective of shifting interests in the field of occupational health and serves as an index of progress.

While the limited supply lasts, sample copies of Public Health Service Publication No. 300, "Bibliography of Occupational Health," can be made available from this Division upon request to persons and organizations concerned with health problems in industry. Copies may also be procured from the Superintendent of Documents, Government Printing Office, Washington 25, D. C., for thirty-five cents each.

BLUE SHIELD-BLUE CROSS NEWS

(Continued from Page 321)

average lengtth of hospital stay for all Blue Cross cases from 5.4 days in 1952 to 5.7 days in 1953.

Every twenty-four hours during 1953 Blue Cross participant subscribers used 2,612.3 days of hospital care compared with 2,472.4 days of care during 1952, 543,493.2 days of hospital care were provided throughout the year 1953 compared with 904,901.6 days of care in 1952, an increase of approximately 50,000 days of hospital care.

Every nine hours during 1953, a Blue Cross participant subscriber incurred a hospital bill totalling $1,000 or over, as compared with one every thirty-nine hours during 1952. During the last quarter of 1953, hospital bills of $1,000 or over were incurred every eight hours.

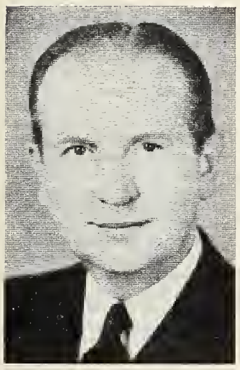
PREVENTION AS A GOAL OF INDUSTRIAL HEALTH SERVICES

LEONARD A. SCHEELE, M.D.
Washington, D. C.



THIS CONFERENCE, it seems to me, represents a kind of partnership that has been a "going concern" for a long time—a partnership of management, labor, the health professions, and government. I would like to take just a few minutes to discuss this relationship.

We used to call this field of health work "industrial hygiene." The new term, "occupational health," characterizes it in a somewhat larger setting, including, nevertheless, the principles of industrial hygiene. The industrial hygiene movement in this country sprang from the initiative of a few progressive business men and the concern of a few physicians, toxicologists, and engineers. From the beginning, its aims were broader than the mere compliance with laws and regulations, often ineffective in bringing about improvements in the health of industrial workers. From the beginning, it was founded on the simple public health principle that "an ounce of prevention is worth a pound of cure."

Prevention—whether of accidents or occupational disease, of communicable or chronic diseases—implies a scientific understanding of causes. Prevention implies a practical means of removing, or minimizing, or controlling the risks of injury, of disease, of disability and death.

The first task of the industrial health movement was to develop the science and skills essential for the prevention of occupational morbidity and mortality. It is in this area of the development of industrial hygiene know-how that the Public Health Service entered partnership with management, labor, and the health professions just about forty years ago.

An Act signed by President William Howard Taft, August 14, 1912, gave the Service its first statutory authority to "study and investigate the diseases of man and conditions influencing the propagation and spread thereof." Prior to that time our research function had been confined to "infectious and contagious diseases." Early in 1913, on the basis of the new law, the Service set up an Office of Industrial Hygiene Investigations in the then Division of Scientific Research. Today, our Division of Occupational Health carries on a similar program of research and development—but in an entirely new environment created by four decades of technological advance and industrial expansion.

The Public Health Service came into the field of industrial hygiene at a time when industry—even large establishments—was spending very little on scientific research into the causes and prevention of occupational diseases and accidents. Then, only two or three State governments had research facilities for this purpose. At the present time, industry is spending many millions for research related to industrial health and safety.

All State governments now have some type of service related to the health and safety of in-

Address delivered at the Upper Midwest Industrial Health Conference, Minneapolis, Minnesota, October 2, 1953.

Dr. Scheele is Surgeon General, Public Health Service, U. S. Department of Health, Education, and Welfare.

dustrial workers, but these services range from factory inspection concerning safety practices to comprehensive programs incorporating research and development. For the most part, however, State programs are not geared to broad occupational health research and in many instances the staff and facilities for consultant service to management and labor are meager.

Research in occupational health, however, is conducted primarily to elucidate the causes and prevention of conditions about which nothing or little is known. It incorporates basic physical and chemical laboratory studies, engineering studies, medical and epidemiologic studies. It is in this area of research that the Public Health Service has been principally active and in which we have made our major contributions.

During two world wars, the Public Health Service was given the responsibility for supervising industrial hygiene services in certain war industries owned and operated by the Federal government. In this work, we naturally investigated recognized hazards and inspected the establishments to determine whether or not industrial hygiene standards were being maintained. Also, in World War II, we loaned industrial hygienists—physicians and engineers—to the States to help them maintain their industrial hygiene service during a critical period. However, we have never operated industrial hygiene programs in private industry. When we go into an industrial establishment, it is at the request of the industry or a State agency with industry consent; and it is then solely for the purpose of conducting industrial hygiene research.

An important factor that has helped to make our contributions in this field significant is this: The Public Health Service is a "silent partner" in occupational health. That is to say, we have no voice in decisions on industrial health—either of the individual industry, or of the labor union, of the State or local government, or of the medical profession. When we get answers to a broad occupational health problem, they become public property in scientific reports. When we get answers, it is the responsibility of industry to apply the findings if it sees fit. It is the responsibility of industrial physicians and engineers to perform the direct services to men and women on the job. This has been the pattern of Public Health Service activity in occupational health since we entered the field. So I say, we are a silent partner; we have no voice in decisions —unless it be the voice of suggestion and reason.

What has been the fruit of this partnership? It is a well known fact that other industrial nations of the world regard industrial hygiene conditions in the United States and the health status of American workers as superior to their own.

Direct injuries from machinery, foreign bodies and similar hazards have been greatly reduced in most industries. Today, industrial accidents represent far less important causes of absenteeism than they once did. States have emphasized controls in this area usually through the activities of their State labor agencies.

Many of the occupational diseases that formerly took a high toll in certain industries have been reduced continuously over the years. Like many of the communicable diseases in the general population, these occupational diseases are no longer major health problems among workers because preventive measures have been widely applied. Among these one-time "black plagues" of industry, we can cite silicosis, mercurialism, lead and phosphorus poisoning.

The physicians who pioneered in industrial hygiene have seen the concept of industrial medicine broaden toward their original vision of a preventive medical service concerned with the total health of the worker. The labor unions and the individual workers no longer regard such services with fear and resistance, but with confidence and co-operation.

How have we accomplished these improvements? The Secretary of the Department of Health, Education, and Welfare gave us a challenging answer in her recent address to the American Federation of Labor. "These accomplishments have been made possible by co-operation," she said, "by working together. But we know that we still have a long way to go. For our goal goes far beyond the elimination of specific occupational diseases and hazards on the job. It looks toward the day in which the worker's total health—mental and physical, on the job and off it—reaches its maximal potential . . . It is plain that this goal can be reached . . . only by the combined efforts of labor, industry, and government."

Yes, we still have a long way to go. But the goal is worth the effort which all of us must make. It seems to me that here in Minneapolis you are involving yourselves in what we may call a way of the future in occupational health. The concern you have for health services in small firms is shared by business organizations, labor unions, medical associations, and governmental agencies up and down the country. But if that concern is to be productive of results, there must be leadership where the problem arises.

The important factor here is that the Minneapolis Chamber of Commerce and the professional associations of this area have taken the leadership to solve a problem affecting the productive capacity, the health and well-being of one of the Nation's great industrial areas. The important factor here, too, is that State and local governmental agencies are partners in this effort.

It was such multiple partnership that sustained the initial work of Dr. Leonard Arling eight years ago in setting up the Northwest Industrial Clinic to serve industries in the Twin-City Area. From the beginning, business associations and the Minnesota State departments of health and of labor and industry have co-operated to broaden the technical services available through the clinic. And today, the Minneapolis Health Department is co-operating through the work of Dr. W. E. Park.

This is the kind of co-operation that our Secretary called the motivating force in attaining the goals of occupational health. When we think of applying this partnership to the task of stimulating industrial health services in small firms, however, we realize that it is a large order.

The lack of health services for workers in small establishments is a problem throughout the country, and one that is growing and becoming more critical as small business expands. Moreover, it is a problem whether we are thinking of the repair shop or the factory, the construction firm or the bank, the public utility or the department store.

I should be less than candid if I did not tell you that—despite the growing concern, despite the pioneer efforts of management and labor, the medical profession and public health agencies—progress in the provision of occupational health services in small firms is discouragingly slow.

America is a nation of small businesses. About 99 per cent of all establishments reporting taxable wages under the Old-Age and Survivors Insurance program employ fewer than 500 persons. About 70 per cent of all employes in the United States are in these small establishments. Yet, less than 5 per cent of these employes in small firms have any type of in-plant, or on-the-job, health services. This is a conservative estimate based on limited studies by the National Association of Manufacturers, the Brookings Institution, various State agencies, and the Public Health Service.

I cannot, of course, give you comparable estimates for Minnesota and the Twin Cities area. However, it is well known that industry here follows the typical American pattern of small business. It seems to me, therefore, that you have in the Twin Cities an unusually good opportunity to demonstrate to the nation as a whole what can be accomplished in the development of constructive, economical industrial health services for small firms.

Is there a need for such services? Here again, national estimates of need are not as precise as we would like to have them. *The National Safety News* for October, 1951, cites figures, however, indicating that accidents occur in small plants about two and a half times as frequently as in medium and large size plants.

The data on sickness absenteeism are not available according to size of plant. The estimated total loss due to temporary disability from all causes is between 400 million and 500 million man-days annually. This does not include the cost to the nation of permanent disability among Americans of working age.

It would be difficult to relate the national estimate of 400 million lost man-days due to accidents and disease to the worker population of the Twin Cities. You get some idea of the magnitude of the local cost, however, by applying the national average of ten days per worker to the Twin Cities' 460,000 or more workers. For Minneapolis and Saint Paul, this means an annual loss of between 4,000,000 and 5,000,000 man-days.

Even if we assume that these losses in productivity, in purchasing power, in expenses for medical and hospital care, and in personal health, occur with equal frequency in small and large business establishments, the distribution of employment tells us that the major portion of the nation's economic loss—the Twin Cities' economic loss—occurs in small businesses.

What can we do about it? Let me say here and now that we do not know all the answers by any means. But it can be said that there have been various experiments here and there, by public and private organizations singly or in co-operation, which begin to suggest some approaches which may lead to the right answers.

In the first place, there is fairly widespread agreement on the objectives of industrial health programs. I found these objectives admirably summarized by Dr. Dale C. Cameron of our Division of Occupational Health.[1] They are:

> "1. The assessment of a worker's physical and psychological assets and liabilities in order to facilitate the selection and proper placement of employes.
>
> "2. The prevention of occupational illnesses and the detection of nonoccupational illnesses in an early stage.
>
> "3. The provision of treatment, the type and extent of which must depend on matters of policy, both local and broad.
>
> "4. The fostering of those physical, mental, and social habits and attitudes which are conducive to both productivity at work and the enjoyment of life."

These are laudable goals, but the practical means of attaining them are by no means as clearly defined as would be desirable. What about costs, for example? Does the program really pay off? Are there supplementary community health services that could be drawn upon to help achieve the goals of occupational health?

A study completed by the Public Health Service in 1952[3] brings together much of the available information on services in small businesses across the country. The striking fact revealed by this study is that there are no reliable cost estimates that could be widely used as guides to the development of such services in individual plants or areas now lacking them.

Obviously, costs are related to the size of the group receiving the service, to the nature and scope of the services, the method of providing the services, and the specific occupational health problems within the establishment. There is, however, an urgent need for well-planned cost-accounting studies that would provide practical guidelines for planning services of varying volume, scope, and content.

The same is true when we are faced with the question: Do industrial health services in small plants pay off? Here again, it is very difficult to get figures that provide clear-cut and reliable answers. In general, the difficulty stems from the fact that small firms seldom keep absenteeism records upon which to base estimates. Also, the majority of small-firm industrial health programs have been in operation for only a few years. In health work, it is necessary to follow the results of a program for a considerable time before a trend can be established. The human organism does not respond to the "play of the market" as quickly as does the sale of products. So, although one's sales chart may reveal day-by-day changes, the curve of sickness absenteeism, compensation costs, and so on will be slower.

In this area of need for sound cost-accounting and statistical studies related to occupational health services, I see an opportunity for American business to make an outstanding contribution to national health. If any institution in our national life has the special know-how, the personnel and facilities to do this job, it is American business. Government cannot and should not do it. Medical organizations cannot do it alone, but they can assist.

Business needs the co-operation of the medical and health professions in developing the kind of data requisite to studies related to occupational health, both in its medical and environmental aspects. In my opinion, we would see much more rapid progress in occupational health if business would more generally apply its special competence to the study of the economic and organizational aspects of occupational health.

The experience of individual businessmen in some small plant programs indicates the catalyzing value of management in occupational health. Their experience also shows that we can get some objective measurements of costs and results.

Mr. Ross Fraser, president of the Rome Cable Company in New York, for example, instituted a complete medical department in his medium sized plant in 1948. He has reported as follows on results in the three-year period, 1948-51: "In 1947 . . . the total man-days lost for all reasons exceeded 9,000. In the first half of 1948, this rate continued. In 1950, compared to the 1947 level, total absences have dropped by almost 50 per cent, with 10 to 15 per cent drop in man-days lost due to sickness. In 1947, we had almost 3,600 man-days lost on which we had no report as to reason, and many of which could probably have been classed as sickness. In 1950, the number (of unaccounted man-days lost) was less than one-quarter of that figure. Man-days lost for occupational injuries were cut to less than one-third of the 1947 level."[2] Mr. Fraser also cited sharp reductions in sick and accident claims and a 43 per cent drop in the cost of compensation insurance.

In a seven-year period, Mr. Ellsworth S. Grant, vice president of industrial relations, of the Allen Manufacturing Company, Hartford, Connecticut, has reported a total reduction in absenteeism from 5.8 per cent to 1.8 per cent. Compensation premium rates were reduced in five years by 24 per cent, despite changes in the Connecticut Workmen's Compensation Act which would normally have led to higher costs. The Allen Company and several other small firms with in-plant health and safety programs have hung up records of more than 2,000,000 man-hours without a single lost-time accident.

These two examples of business experience with small plant health services undoubtedly could be duplicated many times—in this area as well as in other parts of the country. There seems to be no question as to the value of such services, even when objective measures of results are not available.

Management is concerned for the "intangible" as well as the tangible results. Quite rightly, businessmen are concerned with the practical problems of cost and measurable returns. But it is most heartening to hear the repeated assertion that: "Our employes like the service," or that "they are enthusiastic," or "feel that the physicians and nurses have a real interest in their health." One official reports: "The company's health and safety programs, together with group insurance, form a keystone of employe relations; these have contributed substantially to maintaining a high degree of both employe satisfaction and day-to-day employe efficiency."

In this great industrial area, as in others, the Chamber of Commerce, in co-operation with state and local medical societies, health agencies, medical schools, and other institutions, is making concerted efforts to stimulate occupational health services in small firms. It is, as I have said, a large order—and often an uphill battle. But, just as business can and should undertake the practical study of costs, so also the small firms can and should apply their skills in co-operative planning and operation to determine the most effective ways to organize the kind of occupational health service they want. Just as small firms throughout the country have learned the advantages of pooling for the procurement of basic raw materials, so joint planning and agreements might go far to extend the "procurement" of effective health services. I believe that health conferences such as this can provide the essential leadership for such planning and action.

A year or two ago, Dr. Ordway Tead, editor and director of Harper Brothers, came to Washington to conduct a seminar on executive leadership for a group of Public Health Service administrators. I would like to pass on to you his definition of the role of leaders: "Leaders are trying always to influence people, to get something done which needs doing, because the people have come to agree that it's worth doing and that they want to play ball, so to say."

That is a statement in plain terms. It strikes home. But it is deceptively simple, as you will realize when you think it over. For, as Dr. Tead went on to say, leaders are successful in getting the job done to the extent that they are able to involve all the skills and the loyalties and enthusiasms of the folks right down the line. In the promotion of occupational health, this means that the individual workers and their labor organizations, as well as top management and supervisory personnel must be involved in the plans and operation of the program.

Dr. Tead, like many other thoughtful leaders in industry, believes that it is one of the foremost challenges to our society to involve all the folks right down the line in the pursuit of constructive goals. In business, there are various names for this process: industrial relations, employe relations, executive leadership, and so on. Basically, it amounts to the application of sound psychological principles to personal relationships. It seems to me a sign of the times that this conference has stressed this element through the contributions of Mr. Morse, Dr. Hastings, Dr. Stone, and others. For like management and labor, the fields of medicine and public health have come to realize that good personal relationships are fundamental to individual health, happiness, and productivity.

Dr. Cameron, whom I quoted earlier, has estimated on the basis of limited studies in this country and in England, that about 30 per cent

(Continued on Page 335)

HEALTH SERVICE IN INDUSTRY—ROCK FOUNDATIONS

W. E. PARK, M.D.

Minneapolis, Minnesota

ANY BUILDING which is designed to carry a heavy weight of superstructure must have a firm foundation. There are five principal points where support must be sure, at the four corners and in the center.

In the industrial world there must be firm reasons for doing things, and foundations must be well laid. I shall mention five of the rock bottom supports upon which a stable health service may be built. Every one is essential. If any one of the five is missing, the project will not be completely successful and the structure may collapse altogether.

Management Support

First, we must have a progressive plant manager, who is completely sold on the project. He must believe that the health service is a sound business venture. In this respect he need not be in any doubt, for reports from many sources have proven the dollar value over and over again.

One of the first of these value surveys was conducted by Dr. Victor G. Heiser for the National Association of Manufacturers and reported by them in 1941.[1] In this survey all but five of 1,625 companies considered their medical programs paying propositions. The 1951 survey of the same Association gives a similar favorable report.

In 1952, Dr. Kenneth Peacock, in speaking at the Fall Personnel Conference of the American Management Association in New York City, gave before and after figures indicating significant universal profits averaging from $3.50 to $5.00 for every $1.00 spent on Medical Departments. These profits were brought about by such factors as 50 per cent reduction in compensation costs, 30 to 50 per cent reduction in turnover, 30 to 40 per cent reduction in absenteeism, 45 per cent reduction in accident frequency and 63 per cent reduction in occupational diseases.[8]

Because it pays for itself is not the only reason why management needs to give wholehearted support to the health service. There are other less tangible but equally important benefits—the impact on industrial relations;[5] the improvement in morale, company pride and loyalty; the conversion of better general health into better home and community living; to say nothing of the personal satisfaction to an employer.

It is not enough, however, for the plant manager to make funds available for development of a health service. He must be personally interested in its progress and accomplishments. He must give encouragement and inspiration, and be readily accessible, and responsive, when problems arise. He should give the medical director responsibility but not withhold the stimulus of periodic inquiry. The plant manager should acknowledge the superior judgment of the medical director in medical matters but be a tower of support to him in the area of administration.

A Place for "In-plant" Service

The second essential for a firm foundation is a suitable place to work. Every industrialist realizes the advantage of proper space, arrangement of machines and channeling of materials for production purposes, but few are competent to design a health service. Even so, how frequently the doctor or nurse is hired after the rooms have been built. I do not hesitate to say that every health service unit should be designed in consultation with an industrial physician or better still with the doctor who is going to work there. Even before the physical facilities are designed, the extent and limitations of the service should be established. Then the unit can be built to carry out those functions with due regard for later expansion of the service.

We are thinking, of course, of an "in-plant" service. That is, one in which the doctor goes to the plant on a part-time or full-time basis and does most of his industrial work there. In such a setup the physician is paid an adequate retainer fee, which is based on the time he needs to spend at the plant. He should receive no

---

Presented at the Upper Midwest Industrial Health Conference, Minneapolis, Minnesota, October 2, 1953.

Dr. Park is Industrial Health Physician, Minneapolis Health Department.

additional fee, per patient, which would tend to place him on a piecework basis.

I know this is contrary to the thinking of many part-time physicians or doctors on call, who think of industrial medicine as a supplement to their private practices. However, I believe the "in-plant" medical service principle is one of the basic foundations upon which genuine industrial medicine will be built. Is it not time we in the medical profession thought of our services as an essential element of industrial production and, therefore, subject to streamlining for that purpose? It is acknowledged that industry should pay the doctor a reasonable fee or salary for making a careful physical examination of an employe, but industry should not be saddled with the additional expense associated with sending an employe to a doctor's busy downtown office during the plant's working hours. The consequent disruption of production, coupled with the payment of unearned wages is far more costly than the doctor's fee.

I shall not attempt to describe a suitable "in-plant" work place. Suffice it to say, it must be large enough, with proper placement of rooms, quiet enough and private enough to serve its purpose.

Competent Staff

The third foundation stone of an industrial health service is a proper staff. This means a doctor and nurse specially trained and competent to do the job. It also means enough nurses and enough doctor's time to accomplish the purposes and services being undertaken. It should be remembered that the more complete the service the more effective it is. Also as effectiveness is increased, the cost in terms of results goes down.

Training in occupational medicine and industrial nursing is now available as postgraduate courses in some universities. Applicants holding such university degrees have a tremendous advantage over ordinary medical and nursing school graduates. But more than academic training is needed. There is no substitute for experience in a properly conceived and well-operated health service.

One of the musts for a good health service is proper medical supervision. A fundamental concept of a nurse's training is to make her a part of a specialized team, not an individualist. Why then should we expect a nurse to work alone in industry? Every industrialist should realize that it is false economy to hire a nurse and not at least a part-time physician to work with her. And I don't mean a "doctor on call" arrangement.[3] By a "doctor on call" we mean a physician who has consented to respond in case of emergency and advise the nurse when called upon. He, of course, does not get paid for supervising the nurse. The doctor on call has no authority and little influence at the plant. He is not a part of the in-plant team. Only indirectly does he contribute anything to the preventive health program, for instance, through preplacement physical examinations.

The treatment of patients is an important and necessary function of industrial medicine which the "doctor on call" may do very well, but it should be realized that he, like other outside practitioners, stands in the salvage department and not in the production line where the industrial physician belongs.

One thing of paramount importance in an industrial physician or nurse is interest in the work. You can't make an industrial nurse out of a girl who takes a job only to carry her through a few months while she is waiting to get married. The doctor or nurse who will make a success of the industrial health field is the one who sees in it everything he wants in a full and satisfying career.

A Planned Program

The fourth necessary support for a successful industrial health service is a carefully planned program. It is not enough to hire a nurse, give her a first aid station, and tell her to go to work. If she is a nurse, right out of a training school, she won't know what to do. If you are the average employer or personnel director, you won't know what she should do either.

Planning the scope and limitations of a program calls for many hours of discussion between health service staff and other plant personnel including labor representatives. Out of these discussions will grow the medical service procedures and company policies which will govern the service. The medical director should crystalize these procedures and policies by writing them out so that they may become a part of the plant manual.[6]

Of course, the medical service is going to render first aid to the injured. That may be all management wants to undertake. If so, that is a major crippling decision. Under such a policy a nurse may make good window dressing but she is by no means necessary, because someone trained in first aid can do the job just as well. To put a nurse in such a straight jacket is to crush all her enthusiasm for industrial nursing.

A decision should be made as to where to draw the line in the treatment of non-occupational conditions. An industrial health service should not operate in competition with private practicing physicians. Nevertheless, one of the most important factors in absenteeism is non-occupational illness and no industry can afford to ignore it entirely.[4] The usual position taken, is, that the plant physician or nurse will provide dressings and treatments for non-occupational conditions of a minor nature which would not compel the patient to visit his own physician anyway. Such minor service, when available without cost at the plant, many times brings the workman to work when he would otherwise stay home. Another feature of advantage to both workmen and doctors is the early detection of more serious disease which is promptly referred to the private physician for treatment.

The purpose of physical examinations must be clarified. It should be thoroughly understood that the original physical examination will be used to determine the physical capacities of the applicants, with a view to proper placement, and not as a means of rejecting the handicapped or less fit.

How frequently should repeat physical examinations be performed? How much information will be made available to the workman's private physician? What records are necessary and where shall they be kept? How can medical confidences be maintained? How will the health service function in relation to the safety and personnel departments? How vigorously will the doctor and nurse push preventive activities and health education? Shall there be an attempt to enter into medical research or community health and recreational activities? These and many other questions enter into the planning of a health service.

One of the most useful and far-reaching functions of an industrial nurse is health counselling. But not every industrial nurse can do health counselling. It is a capacity which develops with experience and increasing maturity. It is a function which cannot be practiced at the outset but which the nurse may grow into as she becomes accepted and earns the confidence of the employes.

Planning the functions and scope of the health service, and limiting the areas of activity where necessary, is not easy, but it is an important foundation upon which to build. This is the cornerstone which adapts and individualizes the health service to the particular needs of an individual plant.

Proper Attitude

The fifth basic essential of a health service is a proper attitude. When I speak of attitude I mean the attitude of the health service, its medical director, its nursing staff, and behind that the attitude of the plant management.

The foremost proper attitude is the realization that the health service is there primarily for the benefit of the employe. It is his health that is first concern, and this should be a very personal concern. The workman who has acquired skill in the performance of his work is the company's most valuable asset and should be treated as such. Ralph M. Monk, Vice President of the Caterpillar Tractor Co., puts it this way: "The purpose of medical services in industry is not to make money but to make health. Any financial advantage is essentially a by-product and must always be recognized as such."[2]

When the health of the employe is placed first, it is only natural that the plant physician will discuss his findings with the employe and advise him to see his own private physician for treatment of correctable conditions. The employe on his part when he knows that the health service is for his benefit will feel free to use it for advice on medical matters or related problems which require a medical opinion.

It is easy to appreciate the reluctance of a workman to consult the plant physician if he thinks management will be informed of his impairments and his job security thereby threatened. This is a misconception which must be met and eliminated by honest and fair practices.

The relationship of the plant physician to his fellow private practitioners should be most cordial.[7] The plant physician should be constantly working closely with them. He should refer non-occupational conditions to the private physician,

CARE OF HAND INJURIES

ALBERT T. HAYS, M.D.
Minneapolis, Minnesota

"Next to the brain, the hand is the greatest asset to man and to it is due the development of man's handiwork."

IF ONE pauses and considers that quotation for a moment, he realizes the significance and the importance of the preservation or the restoration of the function of an injured hand.

Now, there are many types of injuries to the hand—from the burns, through the lacerations, the amputations, the crushing or squeezing injuries with or without laceration, avulsion or fractures, and finally the complicated compound injuries with lacerations involving tendons, nerves and compound fractures. Inasmuch as it would be impossible to discuss intelligently the care of all types of hand injuries in the alloted time, I am going to limit myself to the most common of all injuries, namely, the laceration, and the most common site, the palm or flexor surface. It is here where what appears to be a minor injury too often proves to be one of a major nature and there develops a loss in the function of a finger or fingers as a result of its improper recognition or handling.

The principal factor which determines the success or failure in the restoration of function of an injured hand is the degree and amount of scarring or fibrosis which results. The greater the degree of scarring and fibrosis, the more interference results in the delicate functioning mechanism of the hand and fingers, namely, the gliding of the tendons through their sheaths or tunnels, the strength of the intrinsic muscle, the flexibility of the joints or the elasticity of the joint capsules. The prevention, to as great a degree as possible, of the development of this fibrosis is one principal which is common to the care of all hand injuries. The extent or degree of development of the scarring and fibrosis is dependent upon many factors from the time of injury through the final stages of rehabilitation. The majority of these factors can be controlled by those involved in the care of the injured hand.

The amount of fibrosis development is dependent upon: first, the extent and severity of the injury; second, the degree of contamination; third, the degree of inflammatory reaction or actual infection which develops, fourth, the proper definitive surgical repair, and fifth, the proper postoperative care and rehabilitation. Obviously, the first two factors cannot be controlled except by safety measures which might prevent the more extensive injuries. The next three factors can be controlled, and their control involves all persons caring for the injured hand, from those giving first aid down through the surgeon and physical therapist.

Once the injury has occurred, the steps in the prevention of fibrosis begins, and it begins in the factory, the office, the store or home.

We will follow through the steps in the care of a laceration in the palm of the hand or finger. The first one to be involved usually will be a fellow worker or someone else in the home. The first step is to prevent further contamination of the wound. The wound is already contaminated by the cutting instrument and the dirt and bacteria on the hand. A dirty handkerchief from a pocket or some rags off a bench used in an attempt to control the bleeding or prevent blood from soiling one's clothing, the floor or rug, further contaminate the wound. Though lacerations of the hand bleed freely, they usually will not bleed to any serious extent until proper first aid can be reached in the plant or home. Let them bleed and let Nature do a little washing of its own until a proper first aid kit is brought to the patient, or the patient is brought to the first aid room. If one is near a water faucet, he should let the water run on the cut and wash away the blood from the hand. All plants or shops or offices which do not have medical departments or first aid rooms should have first aid kits. These kits should be large enough to have sufficient dressings, bandages and tape more than just three 2 x 2 inch squares of gauze, fifteen bandaids and a bottle of iodine or 2 per cent mercurochrome.

Let us assume that the patient is going to be attended by the company nurse, the first aid man or a fellow worker. The attendant may gain some information of the seriousness of the cut by

---

Presented at the Upper Midwest Industrial Conference, Minneapolis, Minnesota, October 2, 1953.

asking the patient to move all fingers, to flex them and extend them completely, and by asking whether any of the fingers are numb. If the finger or fingers cannot be flexed or extended freely in all their joints by active voluntary movements of the patient within what limitations pain or soreness might cause, or if a finger, a part of a finger or several fingers feel numb or asleep to the patient, then we are dealing with a case which requires more definitive treatment than cleansing and bandaging at the plant by the first aid man, nurse or plant physician. Plans should be made for him to be sent to the company's surgeon or preferably his hospital. The first aid care at the plant or home for such a laceration should consist of those things which will lessen the possibility of scarring or fibrosis by preventing further contamination, the development of infection, and the adding of any further trauma, either chemical by irritating antiseptics, or mechanical by injudicious washing, scrubbing, probing or examining the wound. The wound should be covered by sterile dressing and sufficient dressing to absorb the bleeding and then wrapped with bandages snuggly, but not tightly. Usually, a good heavy dressing snuggly applied will control most hand or finger bleeding for the time being, until the patient can have more definite care by the surgeon.

I have not mentioned the use of an antiseptic, and for a purpose. Most antiseptics are fine for killing bacteria, but some of them are irritating to the tissues as well and will produce a tissue response that will increase the development of fibrosis. Especially, time-honored iodine, which even today is frequently dumped or poured on a laceration of a finger or hand, falls into this class. Therefore, if an antiseptic is to be used at all in these more serious lacerations, let it be applied to the finger or hand about the laceration, but not into it. Iodine should *not* be one of the antiseptics in the first aid kit.

The use of a tourniquet has not been mentioned, again with a purpose. A tourniquet is rarely, if ever, needed in lacerations of the hand in spite of what at first appears to be severe bleeding. In the majority of instances the tourniquet is not applied properly, so that usually the veins are shut off and prevent the return flow of the blood and the arteries are not completely shut off so that blood continues to be pumped into the hand or finger, and congestion and swelling develops with damaging of tissues which leads to further fibrosis. As long as we are talking about hands and not arms or legs, the tourniquet is not of special interest.

Now, with the first aid care completed, the hand or finger dressed with sterile and sufficient gauze and bandaged snuggly, the next step is to get the patient to the hospital without delay. An ambulance, siren, police escort or breaking of traffic laws are not necessary, but there should not be unnecessary delay as time is also a factor in our struggle to lessen the development of fibrosis. The longer the contaminants introduced into the wound are allowed to remain, the greater will be the chance of inflammatory reaction or actual infection in spite of our thorough cleansing, debridement and antibiotics.

On arrival at the hospital, the responsibility falls on the medical professional personnel, the emergency room nurse, the intern or resident, and the surgeon. Usually, much information can be gained by questioning the patient and having him move his fingers, if they are exposed, or exposing a part of them to be moved or tested for sensation without disturbing the dressing over the wound itself. If one is still not satisfied and wants to inspect the wound, the inspecting should be done with a sterile aseptic technique similar to that used in the operating room. A mask should be worn by the nurse or doctor. Sterile rubber gloves should be worn and the hand placed on a sterile towel or sheet as the dressing is opened. A sterile instrument should be used in inspecting the wound. One should avoid the excessive sponging of the wound in inspection and should attempt to control the bleeding by pressure proximal to the wound. Probing for tendon ends should not be done. Once it has been determined that tendon, nerves or other important structures have been damaged, the hand should again be dressed and bandaged and preparation made for the definitive surgical care in the operating room. If x-rays are thought advisable for foreign bodies or bony injuries they may be done through the bandaged hand.

It is now the surgeon's responsibility to see that there is no unnecessary delay in getting at the definitive surgery as the contaminants are still present in the wound. These are emergency cases and cannot be put off for hours or until the next morning. Many men feel that definite reparative surgery should not be carried out on the finger after the injury is two hours old or in the hand after four hours. It is also his responsibility to see that the factors, which within his realm, lead to fibrosis are prevented or limited to the greatest degree possible. These factors are infection, additional surgical trauma, injury to or destruction of important structures, chemical irritants which increase tissue reaction, and the too early active movements of healing tissues. His control of the infection factor comes with the thorough cleansing and preparation of the hand and an efficient and thorough debridement. This thorough cleansing and preparation of the hand should be done under a tourniquet and an anesthetic, except some of the smaller lacerations of the fingers which are not too painful or bleeding too severely. I prefer a general anesthetic, even if it entails a stomach lavage in those persons who have recently eaten or drunk. Some men prefer a nerve block. The safest tourniquet is the pneumatic tourniquet or the simple blood pressure cuff. The arm should be elevated for about three minutes before the tourniquet is applied to empty as much as possible the veins of the hand. The cleansing or preparation of the hand should be done by a thorough washing of the hand and that part of the forearm necessary in the preparation, with soap and water, or as I now prefer, pH isoderm with G-11 or so-called pH isohex. Grease or oil may be first removed with ether. Then the hand and wound should be washed with pH isohex and water until as clean as possible without scrubbing or rubbing. This may take a considerable period of time but it is as important as the surgical repair which is to follow. In the cleansing, anything which would add additional mechanical trauma should be avoided as this will cause additional tissue reaction and eventually added fibrosis. For this reason, scrubbing with brushes or rubbing vigorously with coarse gauze should be avoided. The cleansing should be dependent upon the emulsifying action of the soap or detergent and the copious washing with water. What contaminants cannot be washed away can be removed in the debridement. After the cleansing, the hand may be prepared with an antiseptic but if an irritant or alcoholic antiseptic is used it should not be introduced into the wound itself. The antiseptic of choice after a hand has been prepared with pH isohex is aqueous solution of Zephiran or Phemoral. These do not interfere with the antiseptic effect of the pH isohex and can be introduced into the wound without an irritant effect.

Debridement of the wound again involves principles which tend to lessen the development of fibrosis. All contaminating material and devitalized tissue should be removed with the preservation of all viable tissue and the avoidance of injury to the important structures of the hand, and done with the least amount of surgical trauma. This is accomplished by sharp, careful dissection and a thorough knowledge of the anatomy of the hand with ability to recognize its vital structures, especially when under tourniquet.

The next responsibility of the surgeon is surgical repair. This consists of two things: choice of surgery and technical repair. The surgeon must decide which procedure will result in the least tissue reaction in healing and thus the least fibrosis and chances of adhesion or adherence. These procedures are the primary repair of the injured structures or the simple closure of the wound with a secondary repair at a later date. This is dependent upon the type of trauma, the loss of tissue or structures and the location of the trauma. Usually, the more severe the trauma of the injury or the greater the loss of tissue, the greater will be the reaction in healing and the likelihood of scarring and adherence of the primarily repaired structures whose gliding mechanism is all-important. Nerves may be, and should be, repaired primarily, and muscle bellies may be repaired. It is my feeling that tendons severed in the fingers are best repaired secondarily either by simple repair or tendon graft. Those in the hand may be repaired primarily or secondarily depending upon the extent of trauma and damage. Those in the wrist or above can be repaired primarily. When both the profundus and superficial flexor tendons are severed in the palm of the hand or at the base of the fingers the removal of the sublimus with repair of the profundus is preferred whether done primarily or secondarily, especially where the severance is at the same site or level.

In the technical repair of the injured hand the term atraumatic technique has come into use. This implies the careful and delicate handling of the tissues, the use of proper incision and exposures and the use of proper instruments and sutures. Careful and delicate handling of the tissue needs little explanation. It implies the avoidance of unnecessary sponging or rubbing of the tissues, injudicious clamping, spreading of the tissues or continued probing for tendon ends. Incisions for exposure should parallel the flexion creases in the hand or fingers or be in the creases themselves. They should not be made to cross the flexion creases in the palm nor be in the midline of the fingers. These incisions may be made as extensions from the lacerations or be made, as oftentimes is advisable, as separate incisions away from the laceration itself. Frequently, there is less scar adhesions if the original laceration is closed primarily and the injured tendon exposed by an incision at a distance away from the tendon and by the raising of skin and subcutaneous tissue flaps. For exposure in the fingers themselves incisions should be made along the mid-lateral aspects. This position may be found by flexing the finger and placing a dot at the dorsal end of the flexion creases. On straightening the finger a longitudinal incision through these dots will be properly located and be midway between the palmar and dorsal digital vessels and nerve branches. Tendon sheaths and annular ligaments should be opened in this area along their lateral aspects close to the bone. Flaps on the fingers may be made by incisions in the flexion creases connected with the midlateral incisions.

The instruments used should fit the operation. They should be small, delicate and atraumatic instruments which will not crush or damage more tissue than is necessary. Mosquito forceps should be used for clamping; small delicate tissue forceps, small fine-pointed curved scissors with sharp and good cutting blades, small blunt or rake retractor and small sharp scalpel blades should be used.

The suture material should be that which will produce the least amount of tissue or foreign body reaction. It should be as small or fine as is consistant with what needs to be accomplished and minimum in amount. Silk, cotton, linen or wire may be used. My own preference for ligatures is silk about 4-0 to 6-0, and for the repair the technique of Bunnell with the use of fine stainless steel wire and pullout wire and approximating the tendon ends with two or three blood vessel silk right angle sutures. This technique may be used for lacerated tendons in the palm or, where I especially like it, within the tunnels of the fingers where Bunnell's technique of "suture at a distance" leaves a minimum of foreign material at the approximated tendon ends. Silk, cotton or linen may be used for the repair of the tendon but the maintaining of the repair at the approximation should not be dependent upon the strength, size or amount of material but upon the relief of tension by proper position, splinting and immobilization until sufficient healing strength has occurred. If these materials are used, they should be fine (about 6-0) and not crossed back and forth within the tendon, squeezing and devitalizing healthy tendon tissue. Each case with its individual problem dictates the suture or technique to be used. Usually, size 34 wire will suffice for finger tendons, with a slightly larger wire for the pull-out wire. I also prefer the use of wire for closure of tendon tunnels in the finger, using through-and-through mattress wire sutures tied over buttons on the dorsal aspect of the finger.

The repair, like the preparation and debridement, should be done under a tourniquet which is released just before closure so that the larger bleeding vessels may be identified and ligated. The tourniquet is then reapplied until after final closure and dressing. All severed nerves should be sought for and repaired in either the hand or fingers. After closure a sufficiently heavy dessing with snug even pressure should be applied, and the forearm, hand and fingers splinted, immobilizing the fingers and hand in the position of function. This position is similar to one the hand and fingers would assume if a baseball were held in the palm of the hand and the fingers grasped about it and with the wrist slightly dorsiflexed. The hand and forearm should be well elevated postoperatively and maintained that way for several days to reduce congestion to a minimum.

The surgeon's final responsibility is in the postoperative care and in the rehabilitation, and in this he is helped by the physical therapist and also the employer. The use of antibotics, tetanus antitoxin or toxoid is recommended postoperatively, but should never be relied upon to prevent or control infection as a substitute for the careful prevention of contamination, the thorough cleansing and debridement and meticulous aseptic surgical technique. The excellent work of M. L. Mason and H. S. Allen has shown us that in the healing of a repaired tendon the greatest strength and the least amount of fibrosis or scarring is attained when complete immobilization of the tendon is carried out for a period of three weeks. They have shown that in the healing of a tendon three tissues are involved; namely, the tendon itself, the connective tissue in and on the surface of the tendon and the connective tissue surrounding the tendon. This healing begins in the connective tissue in and about the tendon ends with an exudative reaction and fibroblast formation to form a cuff about the tendon ends which is an actual enlargement or swelling. This is especially significant when repairs have been made within tunnels or tendon sheaths where the snugness produced by this swelling or cuff may interfere with the circulation of the tendon or lead to adherence of the tendon to the sheath or tunnel.

Mason and Allen have shown that the healing process passes through three stages of tissue reaction and three phases of tensile strength. The stages of tissue reaction are those of exudation and fibroblast formation, regeneration, and finally maturation which occurs between the nineteenth and twenty-first day. The tensile strength at the approximation diminishes rapidly, becoming its weakest at about the fifth postoperative day. There is then a gradual increase up to the sixteenth day, when it levels off into a plateau until the nineteenth day when it again passes into a phase of increasing strength. Mason and Allen have shown attempted movement or function of the tendon between the fifth and fourteenth day is likely to lead to separation, as well as increased tissue reaction. Also, function or active movement of the tendon after the fourteenth day will not only increase tensile strength but also tissue reaction. After the nineteenth to the twenty-first day, function will further increase tensile strength but with much less tissue reaction, as maturation has taken place, swelling has started to subside and connective tissue elements loosen.

Complete immobilization should be carried out for three weeks. At this time, guarded active movements are begun, with hot soaking of the hand and wearing of the splint at night. At the end of four weeks, active physical therapy is begun and the splint completely discarded. Here the physical therapist takes over. He must guard against too vigorous active and passive movements and massage which will produce swelling of the finger or joints with pain and soreness, and which will retard rather than hasten the return of the functional use of the hand. Finally, the employer may play his part in the rehabilitation of this person by co-operatinng in return of the patient to some form of work of which he is capable. This should be done both for the psychological effect and the fact that there is no better physical therapist than Mother Nature herself in the functional use of the hand.

PREVENTION AS A GOAL OF INDUSTRIAL HEALTH SERVICES

(Continued from Page 327)

of sickness absenteeism is due to emotional disorders. We cannot ascribe a definite proportion of this loss of efficiency to interpersonal relationships in the individual's place of employment. There is good evidence, however, that the impact of modern industrial employment, plus the tensions created by personality conflicts on the job, contributes significantly to emotional and physical disorders among employes. A well-planned medical service, integrated with a safety program and good personnel practices, can do much to ease these tensions and to lessen the impact of the industrial environment.

Sixty-three million people—more than two-fifths of the American population—are engaged in earning a living. When we consider these figures, together with those related to absenteeism, compensation costs, and wage losses due to accidents and disease, we cannot but be impressed with the opportunity which employers and employes, physicians and health agencies, have to promote occupational health—especially in small firms. In so doing, they can make a tremendous contribution to the nation's productive capacity, as well as to its health and happiness.

DIESEL ENGINE DERMATITIS CONTROL

ROBERT PLUNKETT
Saint Paul, Minnesota

IN DISCUSSING the problems of dermatitis in industry, I believe it is well first to determine its relative position as a producer of disability to work. Perhaps a few statistics might serve to clarify this. In New York in 1950, 1½ per cent of the 112,000 cases compensated under the compensation laws of that state were dermatitis cases, and the average compensation paid was $281.00. In the same year in Illinois, less than 1 per cent of the more than 50,000 cases compensated were dermatitis cases, and the average compensation paid in each case was $147.00. The Industrial Commission of the State of Minnesota has advised me that for the years 1948, 1950, and 1952, dermatitis cases represented 2 per cent of the total compensation load.

Thus we see that in our two largest industrial states and in our own state, dermatitis is a relatively minor contributor to the total industrial disability picture. It is, however, the most disabling industrial disease, accounting for 60 per cent of the time lost from work on account of disease.

Though it is difficult to secure comprehensive figures that cover the year by year incident of industrial dermatitis, studies that have been made seem to indicate that larger industries have improved their ability to deal with this problem, with a corresponding decreasing incident, whereas in smaller industries, the incident is somewhat on the increase.

With respect to the railroad industry, from all statistics that are available, it would appear that prior to the advent of the diesel locomotive the incident of occupational dermatitis was so low as to be a negligible factor, and it was not until the diesel locomotive came into extensive use that it assumed any proportions. However, with those railroads that went into an extensive dieselization program during and immediately following the war, the number of occupational dermatitis cases climbed quite markedly. This increase was due, of course, to the tremendous increase in the use of petroleum products and derivatives incidental to the operation and maintenance of the diesel locomotive.

In co-operation with the Association of American Railroads, the petroleum producers, and the manufacturers of cleaners and solvents, the railroad industry generally launched a concerted drive to overcome and, if possible, to eliminate this problem.

At the outset of our studies certain fundamental facts became evident. These in the order of their relative importance might be listed as follows:

It became readily apparent that the petroleum products and their derivatives used to fuel and lubricate diesel locomotives, the chromate compounds used in the cooling systems, and the carbon tetrachloride solutions used in the cleaning of certain parts were all basic irritants, which would produce skin irritation in most anyone exposed to their use for any great period of time, unless proper methods of protection and personal hygiene were followed.

From the information gathered, a planned program was established and carried out. First—we attempted to eliminate from use as many as possible of the irritants; second—we undertook to provide protection in all of our diesel facilities against those irritants we could not eliminate; third—we undertook to improve the washing facilities and to provide proper cleansing agents at all facilities, and, fourth, and most important, we undertook a program of educating our employes to the practice of proper personal hygiene.

It was, of course, impossible to eliminate the use of diesel fuel and we, therefore, improved the methods of servicing the diesels so as to eliminate individual contact and provided protective gloves, aprons, salves and ointments for those most exposed to its handling. In combination with the chemical industry, extensive tests were made to determine if less irritating water solvents than the chromates then in use could be provided, with the result we have now entirely eliminated the use of chromate solutions in our water system, substituting therefor, a non-

---

Presented at the Upper Midwest Industrial Health Conference, Minneapolis, Minnesota, October 2, 1953.

Mr. Plunkett is assistant general claim agent, Great Northern Railway.

irritating but mechanically less effective aluminum base preparation. We have likewise eliminated entirely the use of carbon tetrachloride as a cleansing agent for parts, despite the fact extensive tests have never developed one that was mechanically as effective.

The promiscuous use of protective creams and soaps was eliminated, in our efforts to provide the best protective ointments. We have tested many of them, using one type at one shop and others at other shops, and then by questionnaire and study determined from the users themselves which afforded the best protection. These tests and studies determined there was no one protective cream or ointment that would serve all, and since, to be successful, the program had to meet the needs of each individual, we finally settled upon a standard and now provide five different kinds of protective ointment.

Perhaps the most difficult part of the program was that of educating the men themselves to the fact that carbon tetrachloride, paint thinner, or diesel oil itself, were not the proper cleansers to use after a day's work. As with the protective ointments, we placed in use for test purposes a variety of cleansers with a view to determining the most effective. Here again the study was made with the view to provide the best protection to the individual, and based upon the findings as reported by the men themselves, we are now using two standard cleansers.

All of these studies were made under the supervision of the shop nurse.

As I stated, this program was conducted on an industry-wide basis, and the information gained from the various tests and trials was freely exchanged among the railroads, all benefiting from the experience of the others.

In addition to the above general program, on the Great Northern Railroad, we undertook to make a complete investigation of each case of dermatitis with the view of determining the extent of exposure, the sensitivity of the individual involved, and the desirability of attempting to change the person's type of work. From these studies, it became apparent that in the most stubborn cases, there was very frequently an allergy factor present which was either an underlying cause, or at least a deterrent to rapid and full recovery. We are, therefore, now on the lookout in the examinations of those applying for positions in our diesel facilities for any history of allergy.

Success in a program of this type requires the co-operation of everyone in carrying out the proper procedures; use of protective equipment, the observance of personal hygiene, and a very important factor, the recognizing of early symptoms. Here the shop nurse is of great importance. Co-operation is especially needed from the supervising official, chemists, the shop and roundhouse supervisors, and the safety supervisor and the shop foremen, who must establish regular inspection procedures to determine whether the program is being enforced. Of this group the key man, I believe, is the shop foreman, for it is he who must see to it that instructions on how to wash properly are carried out, that the men change frequently into clean working clothes, that unauthorized protective creams, ointments or soaps are not used, and the proper protective equipment is worn. The best program and plan at higher levels will produce nothing if the foremen do not see to it that it is carried out.

Evidence that our program has been effective, I believe, is the fact that occupational dermatitis on railroads is decreasing. As a matter of fact, the Great Northern Railway Company, though it employs 7,500 men in its shops, roundhouses and stores, does not, at the present time, have one case of hospitalized dermatitis, and only two cases of occupational dermatitis that are keeping the men from work. We are, however, not complacent in our present situation, and we appreciate quite fully that continued success is to be maintained only through preserving and continuing to improve our program. Although we are pleased with the progress we have made, we have attempted to remain ever mindful of the fact that even one case of dermatitis represents a problem to the man afflicted, for whom it is little solace to know he may be the only case out of several thousand employes. When the employe involved is a young man with relatively little seniority, we have normally been able to change him to work that eliminates any exposure without affecting his earnings. However, with the older employes whose seniority has entitled them to preferential jobs and pay, the problem is more acute and not easily solved. We have, however, sought in each such case a satisfactory workable solution.

The job of determining whether or not the exposure was due to carelessness is that of the employer. However, only the examining dermatologist can properly state whether or not the condition is due in any degree to underlying allergy factors. I would suggest that the examining dermatologist take a careful medical history in each case with the view of assisting in determining the extent to which this last factor is present. He should also guard against a tendency to assume that employment in a diesel shop or as an engineman on a diesel locomotive automatically constitutes causating exposure, for, as a matter of fact, at the present time, such is frequently not the case. Perhaps the outstanding proof of the fact that working with petroleum products does of itself constitute dangerous exposure is found in the petroleum industry itself, for it has for many years had one of the lowest incidents of occupational dermatitis among all industrial groups. Here again a carefully taken history will assist the employer in evaluating the case.

I have stated the problem as it relates to the railroad industry because of my limited experience, rather than because of any feeling that we have discovered something new about the control of dermatitis, or that we have had unusual success. To the contrary, all of our plans have been based on work done by dermatologists and other industries years before we became concerned. One of many outstanding examples is the Allis-Chalmers Manufacturing Company of Milwaukee, Wisconsin, who, as early as 1943, undertook a concerted program of occupational dermatitis control and prevention. This program has resulted in a 74 per cent decrease in the incident of dermatitis and a reduction from 10.3 to 2.7 in the number of cases per million manhours of exposure. It is estimated that in two years alone this program effected a saving of over $18,000 in medical and compensation cost.

HEALTH SERVICE IN INDUSTRY

(Continued from Page 330)

of the workman's choice, as naturally as he would to another member of his own clinic. The private physician, on his part, should welcome the inquiries of the plant physician as to the progress of an employe-patient and co-operate by getting him back to work, under the watchful eye of the plant physician, as early as possible.

The attitude of the plant physician should be neutral to both management and labor on matters which are not concerned with health. Where the medical director's professional opinion is required, it should be honest, scientifically sound and based entirely on the medical merits of the case, even though it means a clash with management or labor or both.

Summary

In this discussion I have mentioned five of the foundation stones which are essential if a health service is to succeed. They are:

1. An enlightened, interested and responsive plant manager.
2. A place to work, in the plant, which has been planned and built for the purpose.
3. A qualified and enthusiastic staff, consisting of at least a part-time medical director and a nurse.
4. A well-planned program, which is tailored for the plant served, and written into the plant manual.
5. An attitude of service which places the health of the employe first and maintains a cordial and co-operative relationship with management, labor and fellow practitioners. An attitude of fairness and professional practice which upholds the best in professional ethics and the genuine application of the Golden Rule.

ABSENTEEISM

LOUIS E. NEWMAN
New York, New York

A STORY is told about a sturdy operator of a drop forge hammer in our Lynn plant. One morning his wife appeared at the plant gate to explain her husband's rare absence. She said, in her broken English, "My husband, Joe, can't work today. He was up all night. He couldn't sleep, because, you see, I had a baby last night!"

Any study of absenteeism shows up answers just as surprising as this one. For, more often than not, the people with the best reasons for being absent find a way to get to work—and those with much less reason for absence sometimes fail to come to work. The apparently obvious answers are often not the right ones.

When I first entered the field of industrial health I found a lot of "pat" answers, especially in the field of absenteeism. Answers like—*absenteeism is caused by the absentee-prone. If you weed out the absent-prone you solve your problem.*

By "absent-prone" employe is usually meant an employe who will be among those most frequently absent regardless of the work he does. If there are such employes then it follows that similar proportions of them should be found in large work groups selected at random. It should also follow that the absenteeism statistics should be about the same in similar work groups, if they are of sufficient size to make significant comparisons.

Some of our large plants provide good groups for such a comparison. They have about 2,000 employes in each group; the groups are determined by "the luck of the draw" through a common employment office; the percentage male and female is about the same; the work is similar; *but the absenteeism* rate of one may be double that of its neighbor.

In at least one study made by another company when the so-called absent-prone were removed another group took their place. Also, most of us have seen an "absent-prone" employe change to a normal employe when his home situation was corrected, or his work was changed, or he got a new boss. So it seems unlikely that rooting out "absent-prone" employes will solve the problem.

The second "pat" answer was that *absenteeism among hourly workers doesn't cost anything—that the ones absent are the only ones to lose.*

In fact, one of our manufacturing managers told me that the ones we should go after were the salaried workers, that he had "automatic controls" on the hourly workers by which if they didn't come in they didn't get paid.

He had not faced the fact that when the hourly worker is absent the company had these losses:

1. Extra people on the payroll to take the place of those absent.
2. Idle machinery and unused investment when workers unexpectedly fail to come to work.
3. Disrupted schedules with inconvenienced customers.
4. Higher inventory caused by delay in shipment.
5. Spoilage from substitute workers having to do jobs for which they were not trained.
6. Overtime premiums paid to make up for lost time.

In the case of General Electric our absenteeism the first nine months of this year will average about 5 per cent.* This means that for our billion dollar payroll our employes will not take home approximately fifty million dollars in pay that they would have taken home had they not been absent. It is likely that if we consider the losses to the Company from these absent people that for every dollar our employes failed to take home it costs us one or two dollars additional. These are losses, then, to the employe, to the community, and to the Company.

Instead of using a large company suppose we consider a plant with 300 employes. Such a plant would have an annual payroll of approximately a million dollars a year, so 5 per cent absenteeism would mean a loss of approximately fifty thousand dollars to the employes and between fifty and one hundred thousand dollars to the company. Not all of this can be saved, but some can—enough to much more than pay for the effort.

Presented at the Upper Midwest Industrial Health Conference, Minneapolis, Minnesota, October 2, 1953.

Mr. Newman is Manager of Health and Safety Services, General Electric Company.

*Absenteeism from all causes. It is hours not worked that were planned to be worked, divided by total hours planned to be worked.

The third "pat" answer was that *the way to attack absenteeism was to find out what caused it. That is, was it sickness, personal business; accident; death in the family; or what?*

Isn't it likely that in many cases these are simply *excuses* and not the *reasons* which might be "my job bores me stiff," "I hate the sight of my boss," "I don't think my work group likes me."

One study showed that absenteeism can be broadly classified as: (1) those chargeable to industrial accident or disease: less than 10 per cent; (2) respiratory infections, colds, grip, etc.: 45 per cent; (3) all other causes including personal business, death in the family, etc.: 45 per cent. So, if it is desirable to have some kind of a breakdown of the probable causes of absenteeism, these are probably fair enough.

One of our plants studying this problem concluded that the reasons for their high absenteeism was the fact that their employes traveled an average distance of twelve and a half miles to the plant.

If this were a significant cause of absenteeism then it might be expected that the group of employes journeying over forty miles each day to come to work in this plant would have a much higher absence rate than the group of employes living within a mile of the plant. But a detailed check showed that the employes coming from a long distance had attendance records as good, or better than the employes who lived close to the plant. Absenteeism was more closely tied to motivation than to distance.

The Survey Research Center of the University of Michigan has studied for Detroit Edison Company "What Makes People Absent." They conclude that:

(a) Regardless of the kind of worker, the treatment accorded him will raise or lower his rate of absenteeism,

(b) Doubt is cast that responsible employes come to work regularly and irresponsible ones do not,

(c) Absences both among white collar and blue collar workers are primarily related to *supervision, work associates, job status, and satisfaction.*

You may be surprised to note that no mention of industrial medicine is mentioned as an absenteeism control. Which brings me to the fourth "pat" answer; that *the industrial nurse and doctor can be a prime factor in absenteeism control.*

If a fine modern industrial dispensary staffed with competent doctors and nurses can be a *prime factor* in absenteeism control, why is it that there are such large variances between different departments within the same plant? For example, in one of our typical large plants absenteeism for the third quarter of 1953 was:

	Absenteeism —Male
Department A (over 2,000 employes)	2.7
" B " " "	3.7
" C " " "	5.5
" D " " "	6.8

Each department is equally served by the medical unit; all employes are doing work of a generally similar nature; but, the absenteeism in one department is more than double that of the best of other departments. So it would seem that we should look elsewhere for the major control factor in absenteeism.

If the industrial nurse and doctor are not *prime factors* in control of absenteeism what part do they play? Perhaps one of their most important roles is to show by their treatment of employes that management has a sincere interest in the welfare of employes. This fits in with the modern concept of the industrial doctor being primarily concerned with keeping well people well, rather than simply healing the sick and injured.

There are other things, too, that can be done by the industrial doctor and nurse to lessen absenteeism, but it is doubtful if these will have sufficient influence to be classed as prime factors in control. Some of these are:

1. Good employe placement based on the pre-placement physical examination.
2. Re-location of employes based on periodic physical re-examinations.
3. Special handling of problem cases, including the alcoholic, and those troubled mentally.
4. Rehabilitation programs for employes working at less than capability.

Important as are these and other services performed in the field of industrial medicine, the big area for reducing absenteeism seems to lie more nearly within the control of the employes' own supervisor.

Other comparisons were made to see how absenteeism was related to industry, plant location, size of town, and other factors. But, in each case no simple cause was found to be the answer. One plant, for example, with several thousand employes in one of its Departments had an absenteeism in January of this year of about 8½ per cent. I called the Plant Manager and he said, "Lou, you must remember that this town has pretty rugged winters and the absenteeism figure of 8½ per cent was measured during a single week when we had one of our worst blizzards."

I agreed that that was the probable excuse given for the absenteeism but found it hard to understand why in another Department, employing 4,000 employes in the *same plant,* that during the same week their measured absenteeism was a little over 4 per cent!

What, then, are the factors that effect absenteeism? Well, these things can be said:

Absenteeism gets worse
- with the winter months
- with a higher proportion of female employes
- with high levels of employment
- with prosperous working conditions
- with conflicts in the work group

Absenteeism improves
- with good supervision
- with adequate controls
- with interesting work
- with high "sense of participation" of each employe

Oddly enough, absenteeism seems to improve with some layoffs. The layoffs may increase the turnover rate but drop the absenteeism rate. Probably the reason for this is that employes are afraid they'll be laid off so they either come to work regularly or get another job.

Here are three things that can be done to control absenteeism that are effective and low in cost.

1. *Measure absenteeism, and classify it by foremen.*

In order for management to be able to applaud a good job and criticize a bad job, yardsticks of attendance must be set up. One of the best of these is a report issued monthly, or quarterly, comparing the male and female absenteeism within each foreman's work group with that of each of the other foreman's groups. This report should list each foreman and copies of the report should be sent to every foreman so they can see how they compare with each other.

It is not uncommon to find, when such a report is started, then even though the plant absenteeism averages, say 5 per cent, that it includes foremen who have had groups running under 2 per cent for years, and perhaps one group that has been running over 15 per cent—also for years! But the foremen thought nobody cared about regular attendance; at least not enough to pat him on the back for a good job of getting his people to come to work.

When the report is issued for the first time foremen with poor absenteeism reports are likely to come anxiously into the General Foremans' office with questions about the new report. They will have comments like:

"This is the first time I ever heard that I was responsible for getting my people to come to work!" or

"My record is bad because of those two alcoholics I've got—but they are good mechanics when they're here," or

"My best drill press operator has a farm, and this is his busiest time."

Remarks made by the foremen usually emphasize the fact that they are not going to risk disfavor among their men by being critical of their attendance unless they are forced to it. They don't know how to answer replies like,

"Who's kicking—I'm the guy who don't get paid, ain't I?"

So it becomes important to get to the next step in absenteeism control.

2. *Teach the foreman how to encourage good attendance within his work group.*

One of the most effective things the foreman can do to encourage his employes to come to work regularly is to tell them "they are missed" as soon as they return from an absence. They should learn to greet the returning absentee with factual remarks like,

"Gosh, Joe, when you were out yesterday your machine stood idle all day long."

"You can't run a business with idle machinery," and

"We put Sally on your work yesterday and it was so new to her that she spoiled a lot of pieces. We certainly missed you," or

" . . . and as a result we'll be late in shipment."

In other words, *the emphasis should be put on the fact that the employe was missed, that he was needed on his job,* rather than probing for an excuse for the absence that often uncovers only a good "cock and bull" story.

The Minnesota Society of Clinical Pathologists

THE LABORATORY DIAGNOSIS OF PARATHYROID DISEASE

ELLIS S. BENSON, M.D.
Minneapolis, Minnesota

THE clinical manifestations of both hyperfunction and hypofunction of parathyroid glands are varied and frequently obscure, especially in the early phase. Since early diagnosis makes it possible to avoid debilitating and often irreversible complications, the diagnostic significance of chemical aberrations at a stage in the disease when the clinical manifestations are not outspoken is of utmost importance.

There is no uniform agreement at present regarding the site and mode of action of parathyroid hormone. Evidence suggesting action on bone and on kidney has been presented. Clearly, this hormone plays a major role in the control of calcium and phosphorus metabolism. Following the administration of purified extracts of the hormone four changes take place: (1) immediate, transitory increase in urinary excretion of phosphorus; (2) fall in the serum level of inorganic phosphorus; (3) an approximately simultaneous rise in the serum calcium level and (4) eventual increase in urinary excretion of calcium.

The biochemical abnormalities found in parathyroid disease are strictly in keeping with these hormonal effects. Thus, hyperparathyroidism causes increased calcium and decreased phosphorus in the serum and an increased urinary excretion of calcium. Conversely, hypoparathyroidism is accompanied by decreased serum calcium, increased serum inorganic phosphorus and decreased urinary calcium. No satisfactory method has been devised for the direct assay of the hormone in biologic fluids. Fortunately, then, the biochemical findings in these two conditions provide an indirect but reliable index of hormone function.

Serum Calcium

In interpreting serum calcium findings in the light of parathyroid activity one must keep several considerations in mind:

1. The patient must be *fasting* (an overnight fast is sufficient).

2. The *age* of the patient may be a factor. The normal level of serum calcium in fasting adults has been found to be 10± 1 mg. per 100 cc. of serum so consistently that this may be regarded as a physical constant. Approximately 90 per cent of normal serum calcium levels in adults fall in the range of 9.5 to 10.5 mg. In the period of growth (sixteen years of age or less), the normal serum calcium is somewhat higher, namely 10.5± 1 mg. In infants less than one year of age, a range of 11.0± 1 mg. is considered normal.

3. *Multiple determinations* may be required to establish hypercalcemia in a given instance of hyperparathyroidism because isolated determinations of serum calcium may fall within the normal range.

4. The serum calcium level depends in part on *the concentration of serum protein.* Calcium exists in serum in three physical states which are in equilibrium. Approximately 95 per cent of it is distributed equally between a nondiffusible, nonionized complex with serum protein and diffusible calcium ions. An additional 5 per cent or less exists as diffusible, nonionized calcium citrate.

It has been conventional to consider that parathyroid hormone increased the concentration of ionized calcium and thus affected the level of total serum calcium. Therefore, it would be possible to find the combination of normal total serum calcium, low serum protein and increased ionized calcium in hyperparathyroidism. On the other

---

This is the fifteenth in a series of editorial reports sponsored by the Minnesota Society of Clinical Pathologists and designed to foster closer relationships between clinicians and pathologists.

hand, hyperproteinemic conditions may be associated with increases in total serum calcium without increase in ionized calcium. This would not be consistent with hyperparathyroidism.

Recent studies cast doubt on these conventional views and indicate that the increase in diffusible calcium in hyperparathyroidism is purely a function of the increase in total serum calcium and has no differential diagnostic significance.

Hypoproteinemia generally is associated with hypocalcemia. In hypocalcemia secondary to hypoproteinemia, the diffusible calcium is normal; tetany and hypoparathyroidism are not present.

Serum Inorganic Phosphorus

The significance of decreased serum inorganic phosphorus in the diagnosis of hyperparathyroidism formerly was not fully appreciated probably because attention was focused on the deranged calcium metabolism and skeletal manifestations. More recently it has been realized that low serum phosphorus levels are more frequently found than elevated serum calcium levels. Moreover, the combination of low serum phosphorus and high serum calcium is sufficiently unique to be of great diagnostic significance. This combination has been found rarely in metastatic carcinoma involving bone but for the most part it serves to separate hyperparathyroidism from other bone diseases. Much the same may be said for the combination of low serum calcium and high serum phosphorus in hypoparathyroidism. An elevated serum phosphorus distinguishes this condition from diseases such as rickets, osteomalacia and idiopathic steatorrhea, which often are complicated by hypocalcemia and even tetany.

In general, normal values in adults range from 2.5 to 4.0 mg. per 100 cc., with approximately 90 per cent being 3.2± 0.5 mg. Children and infants have somewhat higher levels; 5.0± 0.5 mg. and 6.0± 0.5 mg. respectively are accepted normal ranges for these two groups. The fasting state is required in this determination.

In hyperparathyroidism the average decrease may be small. Variations occur from day to day. Multiple determinations may be required and the mean of these values used.

When renal insufficiency supervenes, as it may in hyperparathyroidism, the phosphorus levels in the serum may rise, obscuring the classic changes in phosphorus and calcium.

Urinary Calcium

Determinations of urinary calcium are frequently helpful in the diagnosis of parathyroid diseases. A simple qualitative test, such as the Sulkowitch technique, may be used advantageously as a screening test for abnormal excretion of calcium. The composition of the reagent follows: oxalic acid, 2.5 gm.; ammonium oxalate, 2.5 gm.; glacial acetic acid, 5 cc. and distilled water, q.s. ad 150 cc. Five cubic centimeters of reagent is added to 5 cc. of urine in a test tube. The tube is inverted and the results read as follows: 0 = no cloud in 2 minutes; + = fine cloud in more than 30 seconds; ++ = moderate cloud in more than 30 seconds; +++ = moderate cloud in less than 30 seconds and ++++ = curdlike cloud immediately.

The findings are roughly correlated with the level of serum calcium. A negative or low result tends to exclude hyperparathyroidism, except when renal insufficiency is present. A positive result usually excludes hypoparathyroidism. This test also may be of value in regulating the treatment of patients with hypoparathyroidism. Negative results suggest inadequate treatment, while +++ or ++++ results indicate overtreatment.

In hyperparathyroidism, it is frequently necessary to determine quantitatively the amount of calcium in the urine. In this case, the patient should be placed on a low calcium diet for five days. While on this diet it is important to eliminate extraneous sources of calcium, such as tap water and certain medications. During the last three days of the diet, all urine is collected in three twenty-four-hour aliquots and its calcium content is analyzed. Consistent values of 150 mg. a day or less are considered normal. Values of over 200 mg. a day are found in hyperparathyroidism. This finding may be of special value in establishing the diagnosis in cases in which the serum values are of borderline significance. On the other hand, supervening renal insufficiency in hyperparathyroidism may result in low urine values.

Alkaline Phosphatase

An elevated alkaline phosphatase is not a sign of hyperparathyroidism per se but of bone disease. For this reason it is of limited value in establishing the diagnosis in this condition. It is elevated only in that minority of cases associated with actual skeletal involvement; a normal value most definitely does not exclude hyperparathyroidism. In hypoparathyroidism it is uniformly normal. It is well to remember that alkaline phosphatase is elevated in patients with regurgitation jaundice or hepatic metastatic tumors.

Comment

Initially, hyperparathyroidism was described almost exclusively on the basis of its skeletal manifestations. Chiefly through the efforts of Albright its renal manifestations gained emphasis. Its vague and varied symptomatology in the early stages makes it a disease in which a special search is required. The chemical findings are sufficiently characteristic to allow diagnosis in this early stage. The diagnosis should be considered and sought for in patients with:

1. Renal lithiasis. Approximately 5 per cent of patients with renal stones have hyperparathyroidism.
2. Nonspecific skeletal manifestations, such as generalized demineralization.
3. Vague gastrointestinal complaints not associated with definable gastrointestinal disease. Patients with complaints resembling those of peptic ulcer who fail to respond to or whose complaints are aggravated by conventional ulcer dietary regimens may have hyperparathyroidism.

Hypoparathyroidism also may have a vague and insidious course and be versatile in its manifestations. It should be suspected in patients with:

1. Frank tetany or its equivalents, such as paresthesias, numbness, muscle cramps and stridor.
2. Convulsive disorders.

Especially is this so if the patient has had a previous thyroidectomy or is in the first two decades of life. If in association with these neuromuscular disorders, poor dentition, cataracts or ectodermal dysplasias are found, hypoparathyroidism is especially likely. The diagnosis, once suspected, may be established with certainty through the characteristic chemical findings.

ABSENTEEISM

(Continued from Page 341)

3. *Hold the foreman accountable for the regular, on time, attendance of his employes.*

Getting people to come to work regularly is a personal thing best handled by the employe's own boss. Foremen are normally held accountable for control of cost, maintenance of quality, and adherence to production schedules. Regular, on time, attendance of each employe is essential to carry each of these responsibilities.

What is par for absenteeism? Probably about 3 per cent, made up of slightly more than 3 per cent for female and slightly less than 3 per cent for male.

Summary

Effective factors for controlling absenteeism are:

1. Supervisors who recognize their personal responsibility for regular attendance of their work groups.

2. Employes who have such a high regard for their supervisors that they are eager to give their full skill, care, and effort to their jobs.

3. Management who understand that when excess absenteeism is permitted it is like trying to carry profits in a leaking pail.

President's Letter

CHANGING TIMES

Simulating the ideal civilization, the practice of medicine is forever changing, continually improving itself, always making additions and corrections, although often cautious, which manifest themselves in benefits for all mankind.

Certain important changes and improvements have been made in the program of the annual meeting this year, which, it is hoped, will make a favorable impression on physicians attending.

Last month this letter carried a general preview of what doctors can expect to see and hear at the 101st convention in Duluth, June 7, 8, and 9. While it is true that the entire medical meeting is, in effect, a postgraduate course for doctors, there are certain sections of it which should be emphasized, for they mark important changes in the usual format of the program. I would like to tell you about three of the new features of this year's meeting.

Of special interest to the general practitioner are the two consultation booths, which will be among the scientific exhibits on the convention floor.

One, the Orthopaedic X-Ray Consultation Booth, is sponsored by the Orthopaedic Department of the Medical School at the University of Minnesota. Any problems with fractures or other orthopaedic conditions which members or guests wish to bring in and which can be illustrated by accompanying radiographs, will be discussed by the attending consultants.

The other is an Obstetric-Gynecological Consultation Clinic, sponsored by the Association's Committee on Maternal Health and the Minnesota Department of Health. Consultants will be on duty for fifteen-minute individual discussions of current obstetric and gynecologic problems. Two guest speakers, plus several Minnesota physicians, will staff the booth daily.

The other new scientific feature is scheduled for the Wednesday afternoon general session. The entire afternoon program will be devoted to "What's New?" and will present discussions of what's new in medicine, surgery, radiology, pediatrics, obstetrics and gynecology. Department heads of the University of Minnesota medical school will discuss what's new in each of the above fields of medical practice.

These new programs and policies of the 101st annual meeting indicate a growing and healthy organization—and certainly doctors should be intensely interested in keeping their own organization in the healthiest condition possible. Keeping in tune with the changing times, innovations of this type are certain to bring about a bigger and better convention for 1954.

PSITTACOSIS

PSITTACOSIS as a disease in human beings is rarely diagnosed and reported. In 1953, an estimated 100 cases were reported in the entire United States, six cases in Minnesota. The clinical picture is one of fever, headache, early pneumonic involvement, moderate cough, marked prostration, delirium, slow pulse, leukopenia, and albuminuria. The cause of the disease is the psittacosis virus. A rising titer of complement-fixing antibodies to this virus during illness is significant, if accompanied by characteristic clinical symptoms. It is essential that at least two samples of serum or whole blood be submitted to the laboratory, the first during the first few days of illness, the second ten to fourteen days following the first. Early administration of antibiotics may prevent the development of complement-fixing antibodies. There are antigenic relationships between members of the lymphogranuloma and the psittacosis group of viruses.

Psittacosis undoubtedly would be discovered more frequently, if suitable laboratory studies were made more frequently. In the laboratories of the State Board of Health, blood specimens submitted from cases of virus or atypical pneumonia with the request for titration of cold hemagglutinins have been routinely tested also for the presence of psittacosis complement-fixing antibodies. A number of such specimens have been found positive for psittacosis, and clinical symptoms have supported this diagnosis.

Psittacosis became of public health importance during the depression years of the thirties when numerous cases, many fatal, occurred in persons exposed to love birds recently imported from tropical countries, and given away as prizes by carnival companies. Following this experience, practically all states adopted strict regulations forbidding any traffic in psittacine birds, and such birds were generally considered serious health hazards.

More recently the virus causing the disease has been demonstrated in a much broader host reservoir among birds, and psittacosis in man has been traced to turkeys, ducks, chickens, pigeons, and pheasants. Sea gulls and petrels have also been found to be infected. The term ornithosis, frequently used interchangeably with psittacosis, is perhaps a better descriptive title for the disease in light of these facts. In some cases of atypical pneumonia with positive laboratory findings for psittacosis, no association with birds can be determined.

The disease is commonly transmitted to man through contact with an infected bird or the bird's recent surroundings. Occasionally, contact with a human case is responsible for transmission, especially if the patient is coughing. Sick birds are highly infectious, and the birds apparently well occasionally transmit the disease. The disease is more severe in older age groups, and death seldom occurs in persons younger than thirty years. Penicillin and broad spectrum antibiotics are fairly effective in treatment of most cases.

In recent years the practice of keeping psittacine birds as household pets has increased tremendously, and people everywhere are breeding and distributing birds. The impossibility of preventing traffic in such pets, and the fact that human cases were being traced to other types of birds has led most states, including Minnesota in 1952, to rescind the regulations outlawing psittacine birds, and to put more effort into publicizing the hazards and suggesting common-sense methods of avoiding infection. Thus, there is a special danger in making house pets of recently imported psittacine birds or when there is doubt as to recent contact with other and especially with sick birds. Birds should be purchased only from reliable dealers. Shipment of birds from outside the United States is prohibited, and any birds smuggled or bootlegged into this country should be considered as a dangerous potential source of psittacosis. The common practice of permitting such pets to take food from the owner's mouth invites infection, as does any intimate handling of the birds. Pet shops and homes that have harbored infected birds should be thoroughly cleaned before any new birds are distributed from them, and it is good practice to keep new shipments of birds isolated in quarantine for thirty days to eliminate sick individuals. This does not guarantee that the remaining birds are free of infection, but it is helpful.

D. S. Fleming

MALPRACTICE INSURANCE AND ITS COST

YOUR malpractice insurance premiums have been increased. You probably wonder why. You may have a general idea, but have given no serious consideration to the problem facing the medical profession or the insurance companies. Whatever has been your attitude or your interest, the situation is extremely unfavorable and deserves your immediate attention.

Ignorance on the part of members of the medical profession about this important subject is disturbingly evident in spite of effort of insurance companies to bring the matter to their attention. It is also evident that there is a lack of understanding in what the insurance does for the profession as a whole, or how it protects against ruinous losses unless physicians, as individuals, are faced with such a claim or suit. Many have no idea how the rates (premiums) are promulgated. Few understand that the premiums must cover expenses as well as claims and, as a result, believe the insurance companies make fantastic profits. This belief is shared by the same people who believe that all doctors are rich. In the light of these misunderstandings, it is easy to understand why some people support legislative proposals to place automobile liability insurance, workmen's compensation, health insurance and other casualty insurance, under monopolistic state funds and governmental control. It also becomes easy to understand why juries hand out large awards today. Other contributing factors are: Judgments and expense items are paid in terms of inflated dollars. The juryman who pays $2,500 for a low priced automobile and $1.50 for a Blue Plate Special might not hesitate to award a large judgment in a malpractice suit.

The medical practice itself has not escaped social evolution. The personal relationship between the physician and the patient has practically disappeared. Individual practice has been replaced by group practice, clinic and partnership so that the patient does not—except on rare occasions—consult the same physician twice in succession. This may be good medicine, but it has certainly eliminated some of the warm, personal family physician relationship that once existed, plus the fact that the increased use of the hospital has taken an even larger segment of medical practice out of the home and office.

Claims originate in many and divers ways—physicians criticizing another's methods and treatment results, divulging facts about a case or ailment to others, improper diagnosis, improper treatment, and the ever-present fictitious case or hypothetical case.

The methods of correcting the situation are known. Everyone should ask these questions:

Do I follow the rules of my profession?

Do I follow honest and safe practices?

Do I realize that insurance companies are subject to the same economic pressures as my own?

Are claims morally and legally honest?

Are insurance costs in line with my own, considering current conditions, and not conditions of twenty years ago?

Have I opposed socialization of the insurance industry, as I have my own business, remembering when socialism gets its foot in the door in one important branch of the free enterprise system, it will soon be in the door altogether?

In the answer to these questions, you will find the causes for the rising insurance rates.

Don C. Hawkins
Insurance Representative

WORDS AND MEANINGS

NEW WORDS that precisely express a meaning hitherto ineffable are a delight. The exercising of such new words is healthy except when it results in painful repetition. Perhaps as pleasing as acquiring a new word for our working vocabulary is learning the original meaning of an old word or learning the meaning of a similar word in another language than English. Often such information is the means of understanding something that would otherwise have to be retained by brute memory. The abdominal, pancreatic complication of mumps ceased being mystifying, for example, after we recalled that the German word for pancreas was *Bauchspeicheldrüse,* the abdominal salivary gland. The vague significance of malaise became less vague when our friends who fretted with beginning French reminded us that *malaise* meant "bad ease" and thus resembled ill at ease.

The sobriquets applied to members of one nation by peoples of another, usually born of the mingling of nationalities during wartime, are rich in friendly banter and good fellowship, if directed toward allied forces, and as rich in sarcastic deprecation, if directed toward the enemy. Thus, in the pidgin of the Far East, the English soldiers were known as *Assays* from their frequent "I say." The same English soldiery was called *Godon* by the French and *Gadan* by the Spanish, after one of their favorite curses. The Portugese named them *Camones* and the Italians made it *Caman* from their impatient, "Come on, come on!" Italians named German soldiers *Tertòifel* and *Tartàrfel* from their use of *"der Teufel."* Years earlier, the Milanese gave Austrian troops the name *Zuruc* because of their commands to crowds to back up, *"Zurück!"* This recital must be incomplete, but the term, *Damchee,* given to American troops, and finally to Americans in general, by the Indian troops associated with the VIII Army in North Africa, has too interesting an explanation to skip: whenever American soldiers made a purchase, the low price startled them into saying, "Damn cheap," while paying.

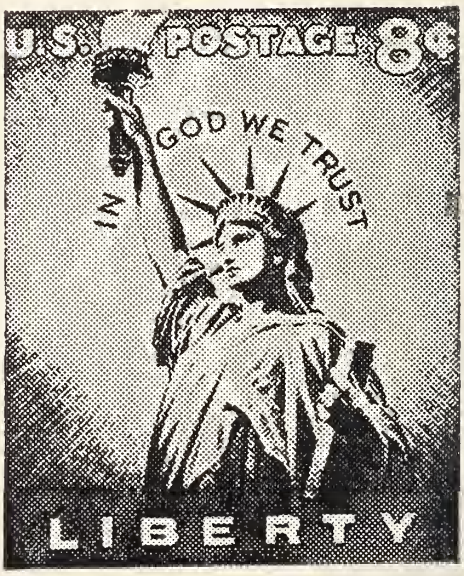
However, the imaginative, occasionally profound, insight some words and word-combinations allow give greater pleasure than these brief excursions into derivations of words. We are told about the language of the Guarani, the Phoenicians of South America, who live in the general area of Paraguay. Their language is essentially a primative one and almost solely a spoken one. It is rarely reduced to writing. The picturesque images drawn by the Guarani words brings the realization that artistry may be found in the everyday conversation of mankind, if the listener perceive the full import of the word combinations. The Guarani speaks not of a "kick" but of a *pï-voi:* the *pi* means foot, and the *vói,* fast or nimble. A kick thus becomes a fast-foot. *Tembé* means lip and *i* means water or a stream. What more logical than that *tembé-i* indicates the banks of a stream? Then in the subjective realm, *guazu* means large and *pïa,* stomach. The combination of the two, *pïa-guazu* adds up to big stomach and is used for courageous. Finally, this crowning jewel of understanding: the same *pia* (stomach) is coupled with *guapi* (seated) so that *pia-guapi* means tranquility. And for how many of our patients do we not wish tranquility via a well-seated stomach? H.G.M.

MINNESOTA MEDICINE—5c

A SURVEY of the past ten years indicates that Minnesota Medicine has cost members of the Minnesota State Medical Association less than five cents a copy during that period. Although two dollars has been allocated from annual dues as a subscription for the journal, all but about sixty cents has been returned to the treasury. The receipts from advertising, reprints, illustrations, and so forth make up the difference. In looking to the immediate future, with the increase in advertising reflected in the past nine months, it is possible that even a lower cost per copy may be achieved.

Your active support of our journal and its advertising benefits both science and organized medicine. If Minnesota Medicine is not what you need, your suggestions will receive careful consideration by the Board of Editors.

NEW STATUE OF LIBERTY STAMP



At the request of thousands of persons, the Post Office has issued a new stamp with a religious sentiment. The new stamp will be used primarily for international mail.

The Dean's Page

THE MEDICAL STUDENTS' ADVISORY COUNCIL

With increasing interest and pleasure, members of our faculty have watched the recent development of an effective, responsible *vox discipulorum,* the Medical Students' Advisory Council. The Council was organized about three years ago for the purpose of advancing "the interest and well being of all medical students and the University." It is made up of the class officers—president, vice president, and secretary—of each of the four classes in the Medical School. The Council in turn selects one member from the preceding year's Council who acts in an advisory capacity. The Dean and the Assistant Dean are also *ex officio* members of the Council.

The Council has concerned itself with a number of problems of interest to students and faculty alike. As one of its major projects, last spring it conducted a survey of student and faculty opinion concerning methods of examination of students, grading and ranking of students, periodic evaluation of the curriculum, and student-faculty relationships. The results of this survey were reported at the regular University Hospital Staff meeting on January 8 of this year and appear in some detail in the Bulletin of that date.* In brief summary, students and faculty agreed on the desirability of some form of periodic evaluation of courses, and both groups indicated that they wanted more opportunities for informal student-faculty discussions. The students were in favor of a simple "pass or fail" grading system with class rank to be determined by a special comprehensive examination and perhaps also by special "honors" work. The majority of the faculty, on the other hand. did not favor such a separation of grading and ranking systems, but most faculty members thought that the grading system could be modified and improved. The students do not like the summer session which has been in effect for the freshman sophomore, and junior classes for the past three years. Faculty reaction on this question was mixed; some faculty members are uncertain of the value of the summer session.

As a result of the survey, the Council has presented to the Medical School Administration several recommendations concerning grading systems and the curriculum. These are now under consideration. The Council has also prepared a questionnaire for the evaluation by the students of the individual courses given in the freshman and sophomore years.

Two other Council projects are worthy of special comment. Members of the Council are co-operating with the Student Counseling Bureau in a plan whereby interested junior and senior medical students will assist in the advising of pre-medical students. The Council is also planning a Pre-Medical Day for the latter part of this month for all pre-medical students at the University and neighboring colleges and for members of next fall's freshman's class. This will provide a fine opportunity for prospective medical students to become acquainted with the Medical School and its faculty.

We believe that members of the Council are to be congratulated for the careful consideration they have given to a number of important problems. I am sure that they do not expect that their suggestions will always result in immediate action. Their recommendations, however, will always be thoughtfully weighed by the administration. New ideas with merit are always welcome whether they originate with students, faculty, or persons unassociated with the Medical School.

George Earl, M.D., Chairman

RUSSIA'S STATE MEDICINE NOTED IN ARTICLE

Surprising and interesting facts are presented on the status of medicine in the USSR in an article carried in a recent issue of the *Journal of the Indian Medical Association*. The article, entitled, "Medicine and Public Health in USSR" was written by A. C. Ukil, of Calcutta, India, and is based on a visit to Russia as a member of a Scientific Delegation from India in 1951.

The article shows, of course, a very decided pro-Russian slant, in view of the geographical and political proximity of the two countries. A sanctioning of the principle of state medicine is evidenced throughout the writing.

The article is of vital interest to American physicians, as it presents a completely pro-Russian, yet factual, view of medicine and public health in the Soviet Union. The author introduces the article with:

> "In understanding the progress in Russia, one has to remember Russia's technological backwardness at the time of the Revolution (1917). Knowing that science has developed more rapidly than society's adjustment to the new conditions created by it, the authors of the Marxist Revolution wanted to make a gigantic effort, by forced marches through successive 5-year plans since 1928, to apply the principles of science to the basic process of life, to production, distribution and consumption in the whole of the Soviet Union. They wanted to banish these by the creation of a Socialist State."

Education—A State Plan

The article describes medical education in Russia in considerable detail, noting,

> "During the first 5-year Plan (1928-32), only 14 medical colleges were opened. Now, there are 73 medical colleges turning out 18,000 medical graduates every year. There is no unemployment. As soon as they pass out, they are immediately offered posts, according to the requirements of the Master-Plan of the country. Stipend-holding medical students, when they pass out, are required to work in rural areas for 3 years. After receiving a broad-based experience there, they are transferred to urban areas or to research institutes as desired by them. The vistas of progress are open to everybody and the social conditions created encourage it."

The scientific delegation visited two medical colleges in Russia, the Second Medical Institute in Moscow and the Medical Institute at Alma Ata. According to the article, the Second Medical Institute at Moscow admits 600 students every year and the total number of students is 4,000. The institution has, attached to it, twelve hospitals with 5,000 beds. Five to seven beds are allocated to each student during "interim" training.

Health—Duty of State

In Russia, the health of the populace is the duty of the state, the article notes:

> "According to Article 120 of the constitution, citizens of the USSR have the right to maintenance in old age and also in case of sickness or disability. This right is ensured by the extensive development of social insurance of factory and office workers at State expense, free medical service for the working people and the provision of a wide network of health resorts for the use of the working people (accommodating 500,000 workers at a time during vacations, with full pay)."

The article continues:

> "The State has also taken over the production of medicaments and their supply to the population. All medical care is free and available to all, regardless of the patient's resources. The State's aim is not merely to cure disease but to prevent it, by creating such living and working conditions as would make the occurrence of disease rare."

Medical Service in Russia

In 1913, according to the same article, there were only 20,000 qualified doctors in Russia. Today, there are 220,000 doctors only under the Ministry of Health, excluding a large number in Railways, industry, et cetera.

Medical and health service throughout Russia are based on a decree issued by Lenin in 1918:

> "(1) To carry through resolutely extensive sanitary sures in the interests of the working people, such as a) improvement of health conditions in populated places (protection of soil, water and air from pollution), (b) organization of public catering on a scientific and hygienic basis, (c) launching of measures to prevent the outbreak and spread of infectious diseases, and (d) creating a code of health legislation; (2) to combat social diseases, such as tuberculosis, venereal diseases, alcoholism, etc.; (3) To make competent medical and pharmaceutical services available to all free of charge."

Distribution Noted

According to Ukil's article, there is, at present, one doctor for 800 people in urban industrial areas and one doctor for 1,000 people in rural areas. There are 10.5 beds per 1,000 people. This ratio prevails all over the union, the article states. Further:

> "With the larger output of doctors as time passes on, this ratio will be further reduced. No doctor, when he passes out, is unemployed. Private practice being practically *nil,* doctors devote their whole attention to the curative, preventive and educative work of raising the health status of the people."

Mass Production Health

In describing medical service in urban and industrial areas, a city is divided into several zones, districts or boroughs, with a district hospital serving about 40,000 to 50,000 people. The article describes the hospital set-up, and it is interesting to note how intricately organized and integrated the political and medical facets are:

> "In each hospital there is a *Board of Medical Control,* consisting of the senior staff, who analyse all cases staying in the hospital for longer than 10 days. . . . In case of urgent surgical or emergency cases the patient first informs the Polyclinic, which immediately informs the Central Emergency Station which must make arrangements to take the case to the hospital, where a bed is vacant, within 20 minutes. The specialists immediately examine the patient and, if there is nothing to the contrary, the patient, in surgical cases, is operated within 15 minutes after arrival in hospital. If there is any violation of this, it is considered as neglect and the Town Council is likely to discuss the matter and recommend necessary disciplinary or organizational steps. . . . The factory population get a health check-up twice a year, while the rest of the population get it once a year."

The article makes this conclusion:

> "Thus the people participate in the health programme from the base to the apex of the health pyramid. Diagnostic and curative doctors and health personnel cooperate at all levels."

Thorough Social Insurance

Complete social insurance is existent in Russia also. It covers the following, noted in the article: (a) medical care, (b) benefits in case of temporary disabilities (sickness, accident, quarantine, pregnancy, childbirth and nursing a sick member of the family), (c) additional benefits for infants, funerals, et cetera, (d) unemployment benefits . . ., (e) invalidity pension, (f) old age pensions, (g) pension to families in case of death of breadwinner. "Social insurance benefits extend not only to the insured workers but also to their dependents."

Other matters are covered in detail in the article, such as the organization and structure of the Health Ministry, regional distribution of medical institutions, medical and health workers' trade union, the production of drugs and instruments, and health resorts and sanatoria.

The pro-Russian bias is seen throughout the article in such statements as: "cooperate fully with the State's efforts to improve health and to prevent diseases," and "in this way, modern scientific diagnosis and treatment are taken to the whole population." Organization of health and medical services in Russia is handled from the top down to the people, and of course, the top is the State, supreme in government and in governing individual rights of medical care of all people.

GERMANY SHOWS SURPLUS OF DOCTORS

According to a recent article in the *St. Paul Pioneer Press,* there is a surplus of 30,000 doctors in Germany. In West Germany, there are 4,543 doctors unemployed or dependent on odd jobs outside the profession. 18,000 doctors have all but deserted the medical field for other careers or are waiting for a chance to set up private practice; and there are 8,000 postgraduate medical students working without pay as interns.

The reason for the whole problem is the complicated traditional German system of public health insurance, including four out of five people in the country. According to the newspaper, "public health insurance in Germany is compulsory up to a monthly income of $100. Voluntary subscription is permitted over the $100 level." Physicians cannot depend on the two out of every 10 patients who can go to private doctors. They must try to become part of the public health insurance system, which is very difficult. The newspaper states:

SOCIAL EVENTS

SUNDAY, JUNE 6

Buffet Supper

American Medical Women's Association, Inc., Minnesota Chapter

6:30 P.M., Home of Elizabeth Bagley, M.D. Open to all visiting women doctors. Dr. Marie Bepko will show colored slides from the Fourth Congress of the Pan-American Medical Women's meeting in New York City.

MONDAY, JUNE 7

Luncheons

Minnesota Chapter, American College of Chest Physicians

12:15 P.M., Parlor B. Hotel Duluth, tickets $2.00

Minnesota Medical Foundation

12:15 P.M., Arrowhead Room, Hotel Duluth, tickets $2.00

Speaker: Clarence Dennis, M.D., New York

Dinners

Minnesota Academy of General Practice

6:00 P.M., Ballroom, Hotel Spalding

Open House, Minnesota State Medical Association
9:00 P.M., Ballroom, Hotel Duluth

Minnesota Radiological Society

6:00 P.M., Social Hour

7:00 P.M., Dinner

Speaker: Philip J. Hodes, M.D., Philadelphia—"An Evaluation of Body Section Radiography" Northland Country Club, 39th Avenue East and Superior Street. Tickets, $5.00. Reservations should be made with Dr. John R. McNutt, 824 Medical Arts Building, Duluth.

TUESDAY, JUNE 8

Breakfast

Former St. Mary's Interns Reunion

7:30 A.M., St. Mary's Hospital

Dinners

Minnesota Society of Clinical Pathologists

6:00 P.M., Annual Dinner and Business Meeting—Home of A. H. Wells, M.D.

Annual Banquet, Minnesota State Medical Association

7:00 P.M., Ballroom, Hotel Duluth

12:15 ROUND TABLES

Duluth and Spalding Hotels

MONDAY, JUNE 7

Anesthesia as a Maternal Mortality Factor
Frederick J. Hofmeister, Milwaukee, Wisconsin

TUESDAY, JUNE 8

Use of Tracheotomy in Chest Injuries
W. P. Eder, Minneapolis

Treatment of Burns in Children
Tague C. Chisholm, Minneapolis

Emergency Treatment of Nerve Injuries
Robert L. Merrick, Saint Paul

Indications and Contraindications for the Use of the Hormones (ACTH and Cortisone) in Gastrointestinal Disorders
J. Arnold Bargen, Rochester

Skin Manifestations in Systemic Disease
John F. Schmid, Duluth

Acute Urinary Obstruction in the Male
Otto C. Phares, Saint Cloud

Drugs in Peptic Ulcer
E. E. Gambill, Rochester

The Injured Hand
J. C. Feuling, Duluth

The Management of Small Bowel Obstructions
Clarence Dennis, New York

Obstetric Hemorrhage as a Maternal Mortality Factor
Charles E. Galloway, Evanston, Illinois

WEDNESDAY, JUNE 9

Diagnostic Difficulties in Carcinomas of the Lungs
F. F. Callahan, Saint Paul

Evaluation of Operations for Peptic Ulcer
C. W. Lillehei, University of Minnesota

Relation of Blood Volume to Gastrointestinal Hemorrhage
J. E. Twomey, Minneapolis

Practical Application of Cytologic Technique for Malignancy
A. H. Wells, Duluth

Anesthesia in Tonsillectomy
F. C. Jacobson, Duluth

Functional Uterine Bleeding
R. F. Sturley, Saint Paul

Treatment of Plantar Warts
R. W. Goltz, Minneapolis

Diagnosis and Treatment of Blood Dyscrasias
Paul S. Hagen, Saint Paul

Significance and Treatment of Lumpy or Discharging Breasts
A. R. Curreri, Madison, Wisconsin

GENERAL SESSION

Duluth Armory

MONDAY, JUNE 7

A.M.

8:30 Visit Scientific and Technical Exhibits.... Armory

9:00 PANEL DISCUSSION ON THE TREATMENT OF HYPERTENSION
Moderator—R. M. Shick, Rochester
Henry A. Schroeder, Saint Louis, Missouri
A. C. Corcoran, Cleveland, Ohio
James H. Currens, Boston, Massachusetts
Robert W. Hollenhorst, Rochester
Question and Answer Period

Intermission

10:15 Visit Scientific and Technical Exhibits.... Armory

11:00 Plastic Operations for Hydronephrosis
Frederic E. B. Foley, Saint Paul
Comments
Ormond S. Culp, Rochester

11:40 Staphylococcal Sepsis; Control with Antibiotics
Robert I. Wise, Assistant Professor, Department of Medicine, University of Minnesota

P.M.

12:15 Miscellaneous Luncheons
Round-Table Luncheon

1:30 Visit Scientific and Technical Exhibits..Armory

2:00 Cancer of the Cervix
A. N. Arneson, St. Louis, Missouri

2:30 RUSSELL D. CARMAN MEMORIAL LECTURE
Pitfalls in the Diagnosis of Pulmonary Diseases
Philip J. Hodes, Professor of Radiology, School of Medicine, University of Pennsylvania, Philadelphia

Intermission

3:15 Visit Scientific and Technical Exhibits..Armory

4:00 SYMPOSIUM ON ANESTHESIOLOGY
Moderator—Ralph T. Knight, Minneapolis
Hypotension During Surgery and the Immediate Postoperative Period
Ferdinand C. Jacobson, Duluth
Cardiac Arrest During Anesthesia
James H. Matthews, Minneapolis
Will Analgesia Evolve from a Century of Anesthesia?
John S. Lundy, Rochester
Trichlorethylene—Its Possibilities for the General Practitioner
O. Sidney Orth, Professor of Pharmacology, University of Wisconsin, Madison

History of Medicine In Minnesota

MEDICAL HISTORY OF THE COUNTY OF YELLOW MEDICINE

MILDRED B. LEE
Granite Falls, Minnesota

(Continued from April, 1954, issue)

Charles William Watson was born in Longford, Ireland, in 1863, and went to Canada with his parents at an early age. His boyhood was spent on a farm near Pilot Mound, Manitoba. After completing his elementary education he came to Minnesota to take his medical training at Hamline University, graduating in 1897.

At that time his brother Dr. James A. Watson was practicing medicine in Wood Lake, Yellow Medicine County, and another brother Frederick G. Watson was a pharmacist and proprietor of a drug store at that place. He seems to have begun his medical practice at Boyd before 1900, for the local papers of that time mention his presence in Wood Lake at various periods, taking over his brother's practice at times, and at other times working with him.

Dr. Charles Watson's service in the county was periodic and probably ended when he left the region in 1909. In 1927 he was located in Minneapolis, but was in poor health and unable to practice. He had contracted an illness which resulted in sleeping sickness.

Dr. Watson died May 15, 1930.

Florado H. Wellcome was born in Stevens Point, Wisconsin, in 1856. In 1858 the family moved to Zumbrota, Minnesota, where they lived for three years, then to Garden City, and finally to New Ulm. Dr. Wellcome was educated in the schools of these villages and took his high school course at Mankato, Minnesota. He then entered Rush Medical College in Chicago, graduating in 1879. He married Mary Taylor, of Madison, Wisconsin, and began his practice of medicine in Granite Falls, Minnesota.

Soon after his arrival in Granite Falls diphtheria became prevalent, and he was on call day and night. This was followed by the epidemic of 1881, when many fell victim to smallpox. An astute businessman, Dr. Wellcome's interests lay in finance rather than in medicine, and although he returned to Rush Medical College in 1884 for a postgraduate course in medicine he spent no small part of his time looking after business interests. About 1883 he took over the loan and collection business of Mr. Teachout, and in the fall of 1884, he announced the establishment of the Yellow Medicine County Bank with himself as president and F. W. Pearsall as Cashier. He advertised his loan business extensively in the papers, and practices in connection with it sometimes resulted in litigation in which it was found that usury was a factor.

In appearance Dr. Wellcome was a large man, of fine physique and regular, rather handsome features. A shrewd businessman, he was able to amass a considerable fortune rather early in life; a circumstance which enabled him to travel extensively in this country and abroad. His sister-in-law, Miss Laura Taylor, accompanied Dr. and Mrs. Wellcome on these journeys and wrote a most interesting account of them which was published in limited edition, beautifully bound, as *Three Westerners Abroad.* It appears that Dr. Wellcome was related to Henry Wellcome, then a member of the English chemical suppliers, or drug firm, of Burroughs and Wellcome which is still in existence. Mrs. Wellcome's forebears also being English they visited the ancestral home of the Taylors also.

Dr. Wellcome discontinued the practice of medicine in Granite Falls about 1885, to devote himself to business. In 1894 he removed to Minneapolis where he became a director of the National Bank of Commerce until its consolidation with the Northwestern National Bank. In 1903 he was one of the organizers of the Union Investment Company, a banking house interested in country banking, farm loans, and commercial business, and became president of this company and several country banks throughout the northwest.

Dr. Wellcome was a member of the Granite Falls Masonic Lodge, and of the Minneapolis, Lafayette, and Minikahda Clubs. He died at the age of sixty-two at his home on 210 Groveland Avenue, Minneapolis, on December 20, 1920. He was survived by his wife, Mary Taylor Wellcome, and three brothers. The only child of the couple, Mamie Wellcome, died at Granite Falls at the age of nine months. A memorial window bearing her name was given to the Congregational Church of Granite Falls.

John L. Wakefield was born in Winsted, Connecticut, in 1823. He received his early training there, and entered Harvard College for medical training. After graduation he began to practice at Winsted under the direction of his father. In 1854 he came west to Shakopee, Scott County, where he lived for a time, becoming one of the first officers of Shakopee Lodge No. 6, A. F. and A. M. In 1861 he was appointed government physician to the Upper Sioux Agency to succeed Dr. Jared Waldo Daniels who had resigned.

Dr. Wakefield and his family took up residence in a large, two-story brick building on the bluffs above the Minnesota River at the site of the Upper Sioux Agency. This house was of solid construction, its walls being fourteen inches thick, and it was only partially destroyed in the Indian uprising of 1862.

Dr. Wakefield's work began with new officials appointed by the Lincoln administration, who were committed to a policy of individualizing the Indians and breaking up their community system. This policy was resented and met with fierce opposition from the Indians. Resentment over the encroachments of the white men and failure of government to live up to promises made to the Indians had been building up for some time, culminating in the hostilities which began August 17, 1862.

Dr. Wakefield was away from the Agency with the Agent when news of the massacre at Acton was brought to the Upper Sioux Agency, and Mrs. Wakefield immediately took her children and set out for Redwood. On the way she was overtaken and picked up by a young man with a horse and buggy. But the attack on Redwood was already under way, and before the party reached that place they were set upon by Indians who killed the young man and took Mrs. Wakefield and her children prisoners.

Dr. Wakefield returned to the Agency later in the day, and was one of the party of twenty-two men and forty women and children who took refuge in the government warehouse. Fortunately for them, the Indians busied themselves with looting and burning the stores, and in the early morning hours John Other Day, a friendly Christian Indian, procured a team and wagon to transport the wounded and children and helped the refugees to get across the river. They had little in the way of arms, ammunition, or food, but the party made its way to Fort Ridgely, which they found under seige. They also found St. Peter under attack, but soldiers from Fort Snelling arrived shortly after the party passed and drove off the attackers. Dr. Wakefield then returned to St. Peter where he helped to care for the wounded.

At the cessation of hostilities Mrs. Wakefield and children were reunited with the doctor, and they settled in St. Peter. In 1869 Dr. Wakefield became postmaster there. He died in February, 1875, at the age of fifty-one years, from an overdose of an opiate. According to his obituary he was "well known and left many friends."

Thomas Smith Williamson was born in March, 1800, in Union District, South Carolina, the son of Rev. William Williamson and his wife Mary Smith Williamson. His grandfather was Thomas Williamson, and his grandmother's name before marriage was Anne Newton, and she was a distant relative of Sir Isaac and the Rev. John Newton. When his father was eighteen years of age he accompanied Gates in his expedition through the Carolinas, and after the war was over he resumed his studies and was graduated at Hampton Sidney College. He then studied theology, and was ordained pastor of Fair Forest Church in April, 1793. The parents and grandparents were owners of slaves, many of whom were purchased at their own request to keep them from being sold to hard masters.

The Rev. William Williamson owned slaves both before and after his marriage, but he did not approve of slavery. In 1805 he removed to Adams County, Ohio, so that he might give his slaves their freedom. Mary Smith Williamson believed that negroes should be taught, and although it was against the law she taught a number of negroes to read and write. In so doing she incurred the hostility of many slaveholders in her husband's parish. This was the chief reason for their going to Ohio. They made the journey by wagon and horseback, taking along the four-year-old Thomas and his infant sister; and behind them in single file trudged twenty-seven slaves who were to be freed upon their arrival in a free state.

Thomas Smith Williamson inherited a deeply religious nature and a sympathetic attitude toward the unfortunate. On completing his elementary education he entered Jefferson College at Cannonsburg, Pennsylvania, graduating in 1820. He then began reading medicine with his brother-in-law, Dr. William Wilson of West Union, Ohio, and after a full course of this, and some practical experience, he took a course of lectures at Cincinnati, Ohio. He then entered Yale College for further medical training and graduated with his degree in medicine in 1824.

Dr. Williamson began his medical practice at Ripley, Ohio, and there met Margaret Poage, daughter of Col. James Poage, a man of wealth and position. On April 10, 1827, Dr. Williamson and Margaret Poage were married. Of her Rev. Stephen Riggs says, "Perhaps no man was ever more blessed with a helpmate more adapted to his wants than this lovely, quiet, systematic, cheerful Christian wife, who for forty-five years of perfect harmony encouraged him in his labors."

In Ripley Dr. Williamson built up a good practice, and in the course of time three children were born. But in the years that followed he became convinced that his life should be dedicated to the service of mankind and God through missionary work. At first it seemed unwise to plan on this, for there were three small children to be cared for. But, the Rev. Riggs states: "God removed this obstacle in his own way—by taking the little ones home to himself." Accepting this hard doctrine of the time, Dr. Williamson placed himself under the supervision of the Chillicothe Presbytery and studied theology, then entered Lane Seminary. He was licensed to preach in April, 1834.

Following this event he was directed to make a survey of the missionary field in the Indian territory, and in doing this journeyed as far west as Fort Snelling. In September of that year he was ordained a missionary, and in April, 1835, he set out with his wife and infant child, Miss Sarah Poage, and the Alexander Huggins family for Fort Snelling.

Dr. Williamson's first activity in Minnesota centered around the Pond mission and he presided at the organization of the First Presbyterian Church, which was the first one established in the territory.

When at Rock Island in 1835, Dr. Williamson had met Joseph Renville, French-Indian trapper and trader and man of many talents and interests. Upon learning that Dr. Williamson was again at Fort Snelling with a missionary party for the purpose of establishing a mission, Renville invited Dr. Williamson to come to Lac qui Parle and establish his mission near the Renville trading post there. This proposal received the endorsement of the authorities, and so on June 22, 1835, the missionary party set out from Fort Snelling in a mackinaw boat loaned by the fur company, to travel up the Minnesota River to Traverse des Sioux. They reached Traverse des Sioux on June 30, and there transferred to a Red River ox cart caravan for the rest of the journey to Lac qui Parle. Dr. Williamson's group traveled by team and wagon from Traverse des Sioux to Lac qui Parle, following the ox carts. The wagon had been taken apart and carried in the mackinaw boat from Fort Snelling to Traverse des Sioux, where it was assembled and put into use. Dr. Williamson drove the team from Fort Snelling along the Minnesota shore, and met the boat at Traverse, where the team was hitched to the assembled wagon. At the time of making this long and arduous journey Margaret Williamson was pregnant. Her son, John P. Williamson, was born October 27, 1835.

For the first year the Williamsons lived at the Fort, Dr. Williamson's first task was to familiarize himself with the Dakotah language. Although languages were difficult for him to learn, he mastered the language, and within two years was preaching to the natives in their own tongue. In 1836 the missionaries chose a site on the north bank of the Minnesota at Lac qui Parle and there began the construction of a mission with the help of Joseph Renville.

The Indians in the territory were very poor and received no annuities from the government. Dr. Williamson and Alexander Huggins set to work to teach better farming methods. Dr. Williamson also practiced medicine, and "for more than a quarter of a century his medical aid went hand in hand with his preaching of the gospel." (Rev. Riggs.) The Indians called the doctor pay-zhe-hoo-ta-we-chash-ta, or Grass Root Man.

Dr. Williamson also began the work of translating the Scriptures into the Dakotah language. In this work he had the help of Joseph Renville, who had been educated in a Jesuit School. But Renville spoke principally French and Dakotah, and so it was necessary for the doctor to learn French also. This, too, he mastered. When, in 1837, Rev. Stephen R. Riggs came to the misson the work progressed more quickly. The Pond brothers had already begun the compilation of a dictionary of Dakotah words, and they had this assistance. It was a work requiring great patience and devotion.

In 1846 the chief of the Kaposia band of Sioux went to the Indian Agent at Fort Snelling and requested that a missionary be assigned to his village. He was alarmed at the deterioration of the tribe due to the liquor furnished them by the saloon keepers of Pig's Eye and other bad influences. The Agent wrote to Dr. Williamson and asked him to take charge of a mission school at Kaposia. In his report of this to the government the Agent added, "He has had charge of the mission school at Lac qui Parle for some years; is well qualified, and is an excellent physician." So in November, 1846, Dr. Williamson moved to Kaposia and took up his work there. He also took a kindly interest in the white people at Pig's Eye, where there was a little log chapel. He was the first to promote education for the half breeds. At his request Miss Harriet E. Bishop came to teach in this, the first school house in Minnesota outside the mission schools.

When the Indians were summoned to a treaty conference at Traverse des Sioux, Dr. Williamson went with them as interpreter and friend. Since the treaty provided for the establishment of a new reservation along the Minnesota River, and agencies to be established at Redwood and Pehijutazi, Dr. Williamson immediately made plans to remove to this new location. In the summer of 1852, he went to Pehijutazi, which was to be the site of the Upper Sioux Agency, and began the construction of a home for his family. In the years that followed other mission buildings were erected, and Dr. Williamson and his staff—which included his own family, and relatives who also shared the missionary spirit, labored there until compelled to leave by the Sioux uprising. At the close of hostilities he did all he could to assist the imprisoned Indians in their prisons at Mankato and Fort Snelling.

After the uprising Dr. Williamson established a home at St. Peter, but he himself devoted two years to the Dakotahs who were imprisoned at Davenport, Iowa. He ministered to their needs, both spiritual and physical, and many Indians were taught to read and write and were instructed in Christian teachings. At the end of three years of imprisonment the Indians were deported to a new reservation at Crow Creek in what is now South Dakota.

The Rev. John Poage Williamson, first of the doctor's children to be born in the Indian territory, was now an ordained minister and missionary sharing his father's work. He accompanied one boatload of 1,300 Indians on the journey to Crow Creek, at the big bend of the Missouri River. Here he stayed for three years, sharing with the Minnesota Sioux the terrible hardships of the time, during which 300 Indians died of disease and starvation. Finally the government released them to a reservation called Santee, near the mouth of the Niobrara River in Nebraska where remnants of the Minnesota Sioux remain today. After the Indians were released, Dr. Thomas S. Williamson accompanied Rev. Riggs and Rev. John B. Renville to Santee, Nebraska, stopping on the way to preach at the Indian villages.

Dr. Williamson continued his work with the Indians for more than thirty-six years. When he was no longer physically able to travel his interest continued, and he attended synods as long as he was able. He continued to work on the Bible translation to the very end. Propped up in bed, he was still at work upon it in his home in St. Peter when death ended his labors on June 24, 1879.

Of the children born to Dr. and Mrs. Williamson, three died in infancy at Ripley, Ohio. Smith Burgess Williamson, "a manly boy," died as the result of an accident while hauling wood for the mission, at the age of fourteen or fifteen years. Lizzie Williamson Hunter died "in the flower of her young womanhood"; Nancy Jane Williamson, born at Lac qui Parle, died at the age of thirty-eight, in 1878. Margaret Poage Williamson, devoted wife and mother, died about 1876.

Dr. Williamson was survived by his son, the Rev. John Poage Williamson, who spent fifty-five years of his life as a missionary in Minnesota, Nebraska, and South

Dakota, and died, still in the service, at the Yankton Indian Agency at Greenwood, South Dakota, in October, 1917. His wife, Sara Van Nice Williamson, died in 1932. John was born in a hut with a dirt floor in Renville's stockade on October 27, 1835, possibly the first white child born in western Minnesota. His knowledge of the Sioux language, learned as a boy, was unsurpassed by any white missionary. He was in constant demand by the Federal government as an interpreter during the Sioux wars.

* * *

Nicolay Hilmar Scheldrup* stems from a famous family that produced outstanding men in Scandinavia from the 16th century on. Originally, the Scheldrup family lived in Denmark, where Bishop Jens Pederson Scheldrup was born in 1524. He must have been an outstanding, brilliant man. After studying philology at the University of Copenhagen he at one time became professor of Physics at this University. Then his interest shifted to theology and in 1557 became bishop of the Bergen territory. One of his sons, Peder Jensen Scheldrup, born in 1571, studied in Denmark and with the renowned ministers school at Wittenberg, Germany. First he was pastor in Fredriksborg and in 1622 he, too, became a bishop (for the Trondheim territory). One of Peder Jensen's sons, Nils Pederson Scheldrup was assistant pastor in Trondnes when he died in 1693. Anders Nilson liked the natural resources and acquired much land outside of Trondnes; there his widow and children settled after his death and the estate remained in the Tovik-Scheldrup family. One of Pastor Anders Nilson's sons, Peder Anderson Scheldrup, was born about 1690; he became district physician in Tovik—apparently the first physician of note in the Scheldrup family tree. Another son held a similar position in Harstad and a third son, Anders Pedersen, was a writer. The latter's son, Nils Anderson Scheldrup, was a shipowner and merchant in Tovik, and his grandson, Anders Martin Scheldrup, born about 1845, was the father of Dr. N. H. Scheldrup. Anders Martin also was a shipowner and merchant. Indeed, a line of ancestors of which to be proud. His mother was Hannah Wanvik.

Dr. Scheldrup finished high school in Norway and left for America in 1891. It is therefore not likely that he graduated from the University of Christiania. He studied medicine at Rush Medical College, from which he graduated in 1897, and later specialized in surgery. He was not the only one in his family to choose this specialty, as one relative became professor of surgery at the University of Oslo.

On August 5, 1907, he married Eva Dunsmore Rose; it was the second marriage for both.

For fifty years, he spent his summers at his summer home in Ontario and his hospitality became famous. For many years, he enjoyed his fine yacht and traveled with it a great deal. His interest, aside from medicine, included ornithology, astronomy, religion and history. He was a great reader and accumulated a fine large, library.

HEBREW MEDICAL JOURNAL ISSUES TWO TWENTY-SIXTH ANNIVERSARY NUMBERS

The *Hebrew Medical Journal* completed its twenty-sixth year by issuing two volumes in 1953 under the editorship of Moses Einhorn, M.D., of New York. Written in Hebrew, with English summaries, the journal has played an important part in the creation of a medical literature and terminology in the language of the Bible. Such a terminology represents an important linguistic and scientific achievement and materially accelerated the rise of a medical literature in Hebrew. To this literature, The *Hebrew Medical Journal* is also making substantial contributions.

Among the articles in the *Spring issue,* Volume 1, 1953, is the section on "Israel and Health." Dr. Meir Yoeli of the Hebrew University in Jerusalem presents a treatise on "Tropical Diseases in Israel." In his article, Dr. Yoeli emphasizes the growing trend of tropical diseases to spread to non-tropical countries as a result of population transfers. He also gives statistical studies on the recent incidence of tropical diseases in Israel, describes the special position of the country as being "on the cross roads of infection," and concludes with a report on recent progress in controlling those diseases in Israel. Another contribution of interest is the manuscript of a medieval Hebrew treatise on "Melancholy" (12th Century), with valuable notes and commentary, by Zussmann Muntner, M.D., of Jerusalem.

In the *Fall issue,* Volume 2, 1953, is the paper by Dr. Edward Tolstoi on "Treatment of Diabetes Mellitus by the Clinical Approach." In this number is included a symposium on "Artificial Insemination." Dr. Abner I. Weisman writes on "Some Consideration on the Status of Artificial Insemination in the United States of America," and Dr. Akiba Joel discusses "Artificial Insemination in Israel." Rabbi I. Jakobovits, Chief Rabbi of Ireland, gives a clarification on the attitude of Judaism, Catholicism and Protestantism towards the subject of "Artificial Insemination, Birth-Control and Abortion."

In the section called "Israel and Health," Dr. A. A. Schwarzbart deals with the increase in the number of tuberculosis cases, which followed the huge influx of newcomers from culturally and economically backward countries after the establishment of the State of Israel, and reports on the success achieved by the treatment of the malady with antibiotics.

✦ Reports and Announcements ✦

FAMILY DOCTORS' DAYS

at the

University of Minnesota Hospitals

All physicians are cordially invited to attend the following Family Doctors' Days which will be presented under the direction of the department indicated.

June 2—Dept. of Pathology

July 14—Ear, Nose, and Throat

Activities begin with luncheon at 12:15 noon with the staff of the department in the Hospital Dining Room and will continue throughout the afternoon.

For further information, write the head of the department concerned or the Director, Department of Continuation Medical Education, University of Minnesota Hospitals.

AMERICAN CONGRESS ON OBSTETRICS AND GYNECOLOGY

The sixth American Congress on Obstetrics and Gynecology will be held at the Palmer House, Chicago, December 13-17, 1954.

The five-day meeting is sponsored by the American Committee on Maternal Welfare, Inc., and the American Academy of Obstetrics and Gynecology. It will bring together the four major groups concerned in the provision of better care for mothers and babies—medicine, nursing, public health and hospital administration.

The program will include twenty-seven formal papers, twenty-two symposia and panels, luncheon discussion groups, and several hundred round-table discussions, covering every phase of maternal and newborn care. Scientific and technical exhibits are also being planned.

Information about the meeting may be obtained by writing to the Sixth American Congress on Obstetrics and Gynecology, 116 South Michigan Avenue, Chicago 3, Illinois.

AMERICAN CONGRESS OF PHYSICAL MEDICINE AND REHABILITATION

The 32nd annual scientific and clinical session of the American Congress of Physical Medicine and Rehabilitation will be held September 6-11, 1954, inclusive, at the Hotel Statler, Washington, D. C.

Scientific and clinical sessions will be given September 7, 8, 9, 10 and 11. All sessions will be open to members of the medical profession in good standing with the American Medical Association.

In addition to the scientific sessions, annual instruction seminars will be held. These lectures will be open to physicians as well as to therapists, who are registered with the American Registry of Physical Therapists or the American Occupational Therapy Association.

Full information may be obtained by writing to the executive offices, American Congress of Physical Medicine and Rehabilitation, 30 North Michigan Avenue, Chicago 2, Illinois.

Annual Essay Award

To stimulate interest in the field of physical medicine and rehabilitation, the American Congress of Physical Medicine and Rehabilitation will award annually a prize for an essay on any subject relating to physical medicine and rehabilitation. The contest, while open to anyone, is primarily directed to medical students, interns, residents, graduate students in the pre-clinical sciences and graduate students in physical medicine and rehabilitation.

The following rules and regulations apply to the contest:

1. Any subject of interest or pertaining to the field of physical medicine and rehabilitation may be submitted.
2. Manuscripts MUST BE in the office of the American Congress of Physical Medicine and Rehabilitation, 30 N. Michigan Ave., Chicago 2, not later than June 1, 1954.
3. Contributions will be accepted from medical students, interns, residents, graduate students in the pre-clinical sciences, and graduate students in physical medicine and rehabilitation.
4. The essay must not have been published previously.
5. The American Congress of Physical Medicine and Rehabilitation shall have the exclusive right to publish the winning essay in its official journal, the *Archives of Physical Medicine and Rehabilitation.*
6. Manuscripts must not exceed 5,000 words (exclusive of headings, references, legends for cuts, tables, etc.), and the number of words should be stated on the title page. An original and one carbon copy of the manuscript must be submitted.
7. The winner shall receive a cash award of $200, a gold medal properly engraved, a certificate of award and an invitation to present the contribution at the 32nd Annual Session of the American Congress of Physical Medicine and Rehabilitation at the Hotel Statler, Washington, D. C., September 6-11, 1954.
8. The winner shall be determined by the Annual Awards Committee composed of four members of the American Congress of Physical Medicine and Rehabilitation.
9. All manuscripts will be returned as soon as possible after the name of the winner is announced.
10. The American Congress of Physical Medicine and Rehabilitation reserves the right to make no award if, in the judgment of the Annual Awards Committee, no contribution is acceptable. The Congress may also award certificates of merit to contributors whose essays may be considered second and third best submitted. Announcement of the winner will be made after the annual meeting. Officers and members of the American Congress and the American Society of Physical Medicine and Rehabilitation are not eligible for this award.

SUMMER CAMP FOR DIABETIC CHILDREN

A summer camp for diabetic children will be opened for the sixth season under the auspices of The Chicago Diabetes Association, Inc., from July 18, 1954 to August 8, 1954 at Holiday Home, Lake Geneva, Wisconsin.

Physicians are requested to notify parents of diabetic children and to supply the names of children who would like to attend camp. Applications may be obtained from, and inquiries should be addressed to: The Chicago Diabetes Association, 5 South Wabash Avenue, Chicago 3, Illinois. Telephone: Andover 3-1861.

NATIONAL SOCIETY FOR CRIPPLED CHILDREN AND ADULTS

The 1954 convention of the National Society for Crippled Children and Adults, the Easter Seal Society, will be held November 3-5, at the Statler Hotel, Boston, Massachusetts.

Convention sessions now being planned, will be geared to the over-all theme of rehabilitation, with general sessions, institutes, seminars, workshops and roundtables on various specialized subjects.

In this thirty-first national convention of the Easter Seal Society, authorities in every area related to helping the crippled will participate. The 1954 convention will highlight the latest thinking and the newest practical developments in the various fields of work with the crippled. A traditional feature will be the Handicapped Panel, comprising persons who have successfully overcome major handicaps to lead useful lives.

The Easter Seal Society, the oldest and most comprehensive organization of its kind, extends 874 specific services and facilities to thousands of crippled persons each year. It does this through the efforts of 1,253 affiliates in the 48 states, the District of Columbia, Alaska, Hawaii and Puerto Rico.

COURSE IN CARDIOVASCULAR DISEASES

A course in cardiovascular diseases for general physicians was presented by the University of Minnesota and the Minnesota Heart association, March 22 to 24, in the University's Center for Continuation Study.

In conjunction with the course, Dr. Samuel A. Levine, clinical professor of medicine, Harvard university, presented the annual George E. Fahr lecture March 23, in Owre amphitheater. His topic was "Some Pitfalls in the Care of Cardiacs."

Director of the course was Dr. C. J. Watson, head of the University's department of medicine. On the faculty were staff members of the University medical school and the Mayo Foundation at Rochester.

Divisions of the course were "Examination of the Cardiovascular System," "Therapy of Congestive Heart Failure" and "Selection of Patients for Cardiac Surgery."

MINNESOTA SOCIETY FOR THE MENTALLY RETARDED

The fourth annual convention of the Minnesota Society for the Mentally Retarded will be held Friday and Saturday, June 4 and 5, at the Hotel Nicollet in Minneapolis. Chief speaker for the convention will be Dr. Salvatore Dimichael, newly appointed executive director of the National Association for Retarded Children, who will fly from New York to speak at the Saturday noon banquet. Dr. Dimichael's topic will be: "The Present and Future in a National Program for the Mentally Retarded." Before joining the NARC early this year, Dr. Dimichael was with the Federal Office of Vocational Rehabilitation in Washington, D. C.

Registration for the convention begins at noon, Friday, June 4. The afternoon will be spent in visits to various schools, workshops and clinics which work with the retarded. A reception from six to seven p.m. will give conventioneers a chance to meet with one another. From seven to nine p.m. there will be workshops in the areas of education for the retarded, publicity and public relations, legislation, fund-raising, and expanding horizons through new group organization. Business sessions will occur Saturday morning from nine to twelve.

Of especial interest to professional persons, as well as to parent-members of the Minnesota Society, will be three forums from 2:30-4:30 Saturday afternoon. These forums will consider: (1) the education of the retarded child, (2) institutional care, and (3) care of the retarded child in the home. Prominent persons from the fields of education and welfare, as well as parents, will analyze the problems in these three areas and discuss solutions, after which discussion from the floor will follow.

Mr. Arthur Gunderson, 821 Summit, Minneapolis, 1953-1954 president of the Minnesota Society for the Mentally Retarded, extends a cordial invitation to all medical, welfare and institutional personnel, teachers, future teachers and all friends of the retarded to attend the convention.

MINNESOTA ACADEMY OF OCCUPATIONAL MEDICINE AND SURGERY

The annual meeting of the Minnesota Academy of Occupational Medicine and Surgery will be held at 6:30 P.M. on May 26, at the Minneapolis Athletic Club.

MINNESOTA SOCIETY OF NEUROLOGY AND PSYCHIATRY

The Minnesota Society of Neurology and Psychiatry held its March meeting at the Town and Country Club in Saint Paul. Dr. Burtrum C. Schiele, Minneapolis, and Dr. Philip M. Margolis, Saint Paul, spoke on "Clinical Experience in the Use of Succinylcholine Chloride in Electroshock Therapy."

In Memoriam

VERNE SEYMOUR CABOT

Dr. Verne S. Cabot, Minneapolis surgeon, died at the age of sixty-four, March 9, 1954, at his home in Minneapolis. He had been absent from his office in the LaSalle Building since last August, but had planned to return to active practice soon.

Dr. Cabot had practiced medicine in Minneapolis since 1913. He was born at Faribault and received his medical degree from the University of Minnesota. He served his internship at Minneapolis General Hospital and took postgraduate training in surgery at the North Chicago Hospital, as assistant to Dr. Carl Beck, and at Cook County Hospital in Chicago. He served for two years during World War I in the Surgical Service of the United States Army Medical Corps in France. He was a member of the staffs of Deaconess, Swedish, and St. Barnabas Hospitals in Minneapolis, and served as Chief-of-Staff of St. Barnabas.

Among the professional organizations of which Dr. Cabot was a long-time member are the Hennepin County Medical Society, the Minnesota State Medical Association and the American Medical Association. He was also a member of the American College of Surgeons, of which he was a Fellow, and of the Minneapolis Surgical Society, the Professional Men's Club and the Business and Professional Men's American Legion Post.

He was one of three brothers, all of whom were physicians and one of whom, Dr. Clyde M. Cabot, survives him. A brother-in-law, Dr. Arthur A. Wohlrabe of Minneapolis, is also a physician.

Other survivors beside Dr. Clyde M. Cabot, are his wife, the former Emma M. Miner; a daughter, Mrs. Charles D. Hellberg; a son, John S.; three grandchildren; and a sister, Mrs. Arthur A. Wohlrabe.

THEODORE A. ESTREM

Dr. Theodore A. Estrem, seventy, died April 8, 1954, after a long illness at his home in Hibbing. He went to Hibbing thirty-five years ago as member of the staff of Rood Hospital. Later he became affiliated with the Mesaba Clinic, specializing in urology and in obstetrics and gynecology.

Dr. Estrem was born at Petersburg, Nebraska, and received his premedical education at the Jewell Lutheran College and at the Red Wing College and Seminary. He was graduated in medicine from the University of Wisconsin and Rush Medical College and served his internship at St. Luke's Hospital in Chicago.

He served a term as chief of staff of the Hibbing General Hospital and he was a member of the St. Louis County Medical Society, the Minnesota State Medical Association and the American Medical Association. He was also a past president of the Hibbing Chamber of Commerce and the Rotary Club and a member of Mesaba Lodge 255 A.F. and A.M., the Algonquin and Hibbing Curling clubs and of Our Savior Lutheran Church of Hibbing.

Surviving are his wife, Violet; a son, Theodore A., Jr., Minneapolis; a daughter, Mrs. W. F. Braasch, also of Minneapolis; a brother, Herman, of Albion, Nebraska; six sisters including Mrs. S. Watland, San Francisco; Mrs. C. Radcliff, Olive View, California; Mrs. John Levos, Norfolk, Nebraska; Mrs. R. Levos and Mrs. O. Limbo, both of Oakdale, Nebraska, and Mrs. George Karabel, Tilden, Nebraska; and two grandchildren.

ALCIBIADES A. GIROUX

Dr. Alcibiades A. Giroux, North Mankato pediatrician, died March 11, 1954, at St. Joseph's Hospital in Mankato at the age of sixty-nine.

Dr. Giroux had never recovered completely from an automobile accident, which occurred several years ago, and had been forced to retire from practice as a result of the shock produced by the floods of 1951 which did serious damage to his home in North Mankato. He had practiced in Mankato since 1944 and, before that, in Duluth for many years and, for a short period, at Moose Lake Hospital.

Dr. Giroux was born at Granby in Canada. He received his pre-medical training at St. Joseph's College in Montreal, and his medical education at the University of Montreal Medical Department. He served his internship at St. Mary's Hospital in Duluth and took his postgraduate training in pediatrics at the University of Minnesota Medical School.

He was a member of the Nicollet-LeSueur County Medical Society, the Minnesota State Medical Association, and the American Medical Association.

Surviving are his wife, Katheryn, North Mankato; one daughter, Mrs. Lee Mockrud, Chicago; three sons, Glen, Donald and Richard, and four grandchildren, all of Mankato.

LOUIS WILLIAM KATZBERG

Dr. Louis William Katzberg, fifty, died at Rice Hospital in Willmar, Minnesota, March 17, 1954. He had been staff physician at Willmar State Hospital since 1951.

Dr. Katzberg was born in Adams County, Nebraska, received his pre-medical education at Hastings College, Hastings, Nebraska, and his medical training at the University of Nebraska College of Medicine in Omaha. After a year's internship at Bishop Clarkson Memorial Hospital in Omaha and a short period in practice at Pine Island, Nebraska, Dr. Katzberg moved to Minnesota and became staff physician at the Fergus Falls State Hospital from 1935 to 1939. From 1939 until he went to the Willmar institution in 1951, he practiced at Spring Valley, Minnesota.

Dr. Katzberg was a member of the Minnesota State Medical Association, the American Medical Association and the Kandiyohi-Swift-Meeker County Medical Society.

Survivors include his wife, the former Mabel Richards of Omaha; three daughters, Ann, fifteen, Carol, fourteen, and Sue, twelve; his parents, Mr. and Mrs. Gus Katzberg of Prosser, Nebraska; and a brother, Ralph, also of Prosser.

JOHN RICHARD PETERSEN

Dr. John Richard Petersen, for thirty-five years medical director of the Lutheran Brotherhood Insurance Company, died in Minneapolis, April 4, 1954. He was eighty-two years old.

Dr. Petersen was born in Minneapolis and graduated from Luther College at Decorah, Iowa, and the University of Minnesota Medical School. He had practiced at Willmar and at Renville before joining the insurance company.

He was a life member of the Hennepin County Medical Society, the Minnesota State Medical Association and the American Medical Association. He was associated, also, with the Athletic and Old Guard clubs.

Surviving are his wife, Thea; a son, Richard L. of Park Rapids; a daughter, Mrs. L. S. Carroll, Minneapolis; a sister, Mrs. Clara Ulvilden, Minot, North Dakota; and one granddaughter.

FRANK THOMAS RODWELL

Dr. Thomas Frank Rodwell died at his home in Mahnomen, April 22, 1954, at the age of ninety-three. He was a member of the Fifty Club of the Minnesota State Medical Association and had been honored last year by townspeople as the oldest living Legionnaire in Minnesota.

Dr. Rodwell served for twenty-eight years in the U. S. Indian Service as physician and superintendent at Walker and at White Earth. He moved to Mahnomen to engage in private practice in 1930. A reference to him in Polk's Medical Directory of 1898 indicates that he had been established there before. He continued to practice in Mahnomen on a limited basis until a few years before his death.

Dr. Rodwell was born at Hamilton, Ontario, and received his preliminary education at the Collegiate Institute at Hamilton and at Michigan College (now Wayne University), Detroit, from which he received his medical degree in 1886. He served his internship at Harper Hospital in Detroit and took seven years of postgraduate training at the Hospital of Lumber Casualties at Saginaw, Michigan. He came to Minnesota in 1893.

He was a member of the Red River Valley Medical Society until the time of his retirement, as well as the Minnesota State Medical Association and the American Medical Association. He served in the Army Medical Corps during World War I.

Survivors include his wife, the former Mayme Holden of Brainerd, whom he married in 1904 and two sons, Thomas, of Granite Falls, and Harold, of Mahnomen.

ANTON G. WETHALL

Dr. Anton G. Wethall, Minneapolis urologist, died April 4, 1954, at the age of eighty-two. He had practiced in Minneapolis for more than fifty years and had maintained offices in the LaSalle Building there until a year ago.

Dr. Wethall was born in Norway but came to America with his parents seventy-six years ago, settling in Stoughton, Wisconsin. He received his pre-medical education and a B.S. degree from Valparaiso University in Indiana and his medical training at the University of Minnesota. He interned at Deaconess Hospital and has been on the staff there ever since. He was also a member of the staffs of St. Andrews and Mt. Sinai Hospitals. He took postgraduate work in urology at the New York Post-Graduate School in 1913 and again in 1919, and at the University of Vienna in Austria in 1927.

From 1911 to 1917, Dr. Wethall was clinical assistant in urology at the University of Minnesota. He served as staff instructor from 1917 to 1928 and as assistant professor from 1928 to 1941.

He was a life member of the Hennepin County Medical Society, the Minnesota State Medical Association and the American Medical Association; also he was a member of the American Urology Association, Sons of Norway and the Central Lutheran Church.

Surviving are his wife, Amanda J., and two daughters, Mrs. Clarence A. Kuntz and Mrs. John G. Gustafson, both of Minneapolis.

ARCHA EDWARD WILCOX

Dr. Archa E. Wilcox, surgeon and leader in industrial medicine, died at his home in Minneapolis, April 6, 1954. He was seventy-eight years old.

For thirty-nine years until his retirement in 1941 he was a prominent figure in civic and welfare affairs in Minneapolis, as well as in the practice of medicine. As medical director of the Washburn-Crosby Company, he established the first industrial medical department in this area. He was for some years a member of the Minneapolis Board of Charities and of the Welfare Board. For a short time, also, he was superintendent of Minneapolis General Hospital and he served as chief of the surgical service and head of the medical staff for ten years.

Dr. Wilcox was born in Minneapolis and attended East High School there. He received pre-medical training at the University of Buffalo and his medical education at the University of Pennsylvania. Following internship at the German Hospital in Philadelphia, he took postgraduate training in surgery under the late Dr. John B. Deaver and in Europe. He established himself in medical practice in Minneapolis in 1902, and taught surgery, first at Hamline University and then at the University of Minnesota, where he was associate professor emeritus of surgery at the time of his death.

Dr. Wilcox served as chairman of the Committee on Industrial Health of the Minnesota State Medical Association and he was also a member of the medical panel for occupational diseases for the State of Minnesota.

He was one of the organizers of the former Hillcrest Hospital and he served as chief of staff at both the Abbott and Eitel Hospitals. He was elected president of the Minnesota Academy of Medicine in 1934 and 1935. He was a fellow of the American College of Surgeons and member of the Minneapolis Surgical Society, the Southern Minnesota Surgical Society and the Western Surgical Society. He was a life member, also, of the Hennepin County Medical Society, the Minnesota State Medical Association and the American Medical Association. He belonged to the Minneapolis Club and to the Minneapolis Institute of Arts. During World War I, he was in the reserve officers corps. During World War II, he served on the selective service appeal board.

Music was one of his hobbies. He was a skilled pianist and entertained his friends often at his summer residence, Rippleside, on Elm Creek near Anoka, during his more active days.

Surviving are his wife, the former Mary Hays Hunter; two children, Archa Edward Wilcox, Jr., of Minneapolis, and Mrs. G. Chester P. Gifford, Houston, Texas; two sisters, Mrs. Myrtice Joslin and Mrs. Beatrice Keator, both of Excelsior, and two granddaughters.

GERMANY SHOWS SURPLUS OF DOCTORS

(Continued from Page 351)

"First, the public health insurance law allots one physician to 600 patients under public insurance, and one dentist to 1,250 patients. This allocation of doctors and dentists automatically restricts the number who may practice in the public health insurance field. Further, permission to treat public health insurance patients is not given to all physicians admitted to practice.

"Finally, because of the 'splitting-the-melon' type of payment to the doctors participating in the public insurance scheme, the doctors in the plan are encouraged to oppose any increase in the numbers dividing the lump sum of payments."

In the insurance plan, half of the premium payment is taken out of the wage-earner's pay, the other half is paid by the employer. In addition, a patient pays about 10 cents for a "sick ticket" when he wishes to see a doctor. The article states:

"This means that eight of every 10 patients enter doctors' offices with 'tickets.' The remaining two patients visit private practitioners. However, private practitioners cannot count on drawing two of every 10 patients. Since these latter are presumably well off, at least one of them will take his medical business to a 'professor,' not to a mere 'private practitioner.' The 'professor,' peculiar to German medical practice, is a specialist who, besides drawing a fixed income at the university and possibly as head of a hospital as well, will put his outstanding knowledge and ability at the disposition of a few private patients . . ."

The situation is aggravated by the fact that there are many refugee physicians from German territory behind the Iron Curtain. The refugee medical men also demand—and rightly so, the West German government feels—a chance to establish a private medical practice.

BLOOMINGTON WOMAN GIVEN THREE YEARS PROBATION ON ABORTION CHARGE

Re: State of Minnesota vs. Carolyn Lillian Lilledahl

On March 25, 1954, Mrs. Carolyn Lillian Lilledahl, 37, 9949 Maple Ave., Bloomington, Minnesota, was sentenced by the Hon. Levi H. Hall, Judge of the District Court of Hennepin County, to a term of not to exceed four years in the Women's Reformatory at Shakopee, following her plea of guilty on February 25, 1954, to an information charging her with the crime of abortion. However, Judge Hall stayed the execution of the sentence for a period of three years and placed the defendant on probation during that time.

The defendant Lilledahl did not actually perform the abortion but received $35 of the $200 that was paid for it for acting as the contact between an alleged nurse and the twenty-nine-year-old unmarried Minneapolis woman who submitted to the illegal operation on February 18 and was hospitalized in Minneapolis two days later due to the after-effects of the abortion. Although the abortionist has not been identified, she has been described as being a registered nurse, single, rather attractive, 27 years of age, 5 feet in height, 120 pounds, and having a medium complexion and reddish brown hair, her first name being Marie.

When Judge Hall sentenced Mrs. Lilledahl, who has no license to practice any form of healing in Minnesota, he pointed out that there was no excuse for her becoming involved in an abortion in any manner whatsoever since she knew that her mother was presently serving a sentence for the same offense. Lillian Mullane, the defendant's mother, was sentenced by Judge Hall on October 2, 1953, to a term not to exceed two years in the Women's Reformatory at Shakopee on an abortion charge. While the defendant Lilledahl claims that she does not know the identity of the abortionist her story in that respect is not believed by the authorities.

◆ Of General Interest ◆

Dr. H. A. Wilson, Veterans' Administration Hospital, has been released from the hospital in Spokane, Washington, where he has been recovering from a heart attack suffered while on a hunting expedition. He will be confined to his home for several more months before he will be able to take up his professional duties again.

* * *

The "natural increase"—gain in births over deaths—has been 150,776 since 1950-51, **Dr. A. J. Chesley,** head of the state health department, reported. Minnesota is well past the 3 million population mark, with a gain of more than 100,000 the last three years, raising the total to 3,089,904, according to state department of health figures.

* * *

Dr. J. Garott Allen, professor of surgery at the University of Chicago School of Medicine, spoke at a course in emergency surgery for general physicians at the University of Minnesota April 1-3. Emergency management of various types of wounds and injuries and acute abdominal conditions were stressed. **Dr. O. H. Wangensteen,** chairman of surgery at the University and director of the course, and **Dr. Leo G. Rigler,** head of radiology at the university, led a symposium on intestinal obstruction, April 3. Dr. Allen also delivered the annual Clarence M. Jackson lecture April 1 on "The Management of Acute Upper Gastrointestinal Hemorrhage."

* * *

Dr. C. W. Truesdale, Glencoe, attended the New Orleans Graduate Medical Assembly in New Orleans, Louisiana, in March.

* * *

Dr. Roy H. Good became associated with Dr. Paul Swedenburg, Glenwood, in medical practice on March 1, 1954. Dr. Good is a recent graduate of the University of Minnesota Medical School and previously practiced in southern Minnesota. He is a veteran of three years' service with the United States Navy.

* * *

Dr. Roy Burt, Anoka, spoke to the members of the Cambridge P.T.A. on March 15. His topic was "Mental Health." Dr. Burt is a member of the executive board of the Minnesota congress of parents and teachers, and is chairman of its human relations and citizenship committee.

* * *

Dr. Robert N. Barr, deputy executive health officer of the Minnesota health department, spoke on "Rehabilitation" at the Midway Lions club meeting on March 15.

* * *

Dr. Donald B. Simonson was elected chief of Fairview hospital medical staff at the March staff meeting. Other officers elected were: **Dr. Rudolph W. Koucky,** vice chief; **Dr. Harry B. Hall,** secretary; and **Dr. Maurice G. Gilbert,** treasurer. The executive committee includes the officers and **Doctors Donald B. Frand, Richard C. Gaard, Harold R. Leland, Glenn L. Peterson** and **Ragnar T. Soderlind.**

* * *

Dr. Robert N. Barr, University state health department, was the guest speaker at the Women's section of the Industrial Safety school in Duluth.

* * *

Dr. Warren L. Kilmer, International Falls, left the first part of March to accept a surgical residence fellowship in a Chicago hospital. The fellowship is for a four-year period, and in addition to his residency he will be employed as a physician by the United States Steel Corporation in Gary, Indiana.

* * *

Dr. C. W. Rumpf, Faribault, recently returned from Korea, where he was Deputy Surgeon of the Eighth Army, was the guest speaker at the annual Father and Son banquet at the St. Luke Evangelical and Reformed Church on February 22.

* * *

The story of Swift county's tuberculosis accreditation was related in the March issue of *Everybody's Health*, state Christmas Seal magazine. Pictured in the magazine were residents of Swift County who participated in the ceremony. Speaker at the accreditation, **Dr. L. S. Jordan,** superintendent of Riverside Sanatorium, Granite Falls, made special mention of the tuberculosis control work done by the late Dr. C. L. Scofield of Benson, a pioneer in tuberculosis work in Minnesota.

* * *

Dr. Carl J. Potthoff, Rochester, was one of the featured speakers at the seventh annual interim session of the Montana Medical Association in Helena, March 4 and 5. Dr. Pothoff spoke on "Recent Developments Toward a Vaccine Against Poliomyelitis."

* * *

On Tuesday, February 16, **Dr. R. V. Williams,** Rushford, marked the fiftieth anniversary of medical practice. Dr. Williams is a graduate of Northwestern University, Evanston, Illinois. He spent his internship at Cook County Hospital, Chicago. In February, 1904, he went into practice in Rushford.

* * *

Dr. Agnes Marie Hoeger, medical missionary to New Guinea, now studying public health at the University of Minnesota, addressed the members of Alpha Epsilon Iota, medical sorority at a noon meeting on March 9.

* * *

Inability of state hospitals to hire physicians and psychiatrists because of a shortage of doctors was one of the problems that confronted legislators, hospital officials and others that participated in a mental health conference in Minneapolis, on March 18. The conference was called by **Dr. Ralph Rossen**, superintendent of Hastings state hospital and Minnesota's first mental health commissioner.

* * *

Dr. W. F. Maetz has been appointed to the medical staff of the Anoka State Hospital; he assumed his duties March 1. He practiced in New Prague until about ten years ago when he moved to Saint Paul.

* * *

Dr. Kristofer Hagen, who has been associated with Dr. Theodore Greenfield at the Cokato Hospital since September, 1952, left in March to open a practice in Richfield. Dr. Hagen went to Cokato after serving as a medical missionary in India. Previously he had served with the army in Europe.

* * *

Dr. Richard A. DeWall, Anoka, has left Mork's Clinic to do research work at the University of Minnesota hospital.

* * *

The Minnesota Heart association presented a course in cardiovascular disease in the University of Minnesota Center for Continuation Study, March 22-24. **Dr. Samuel A. Levine,** clinical professor of medicine, Harvard University, presented the annual George E. Fahr lectures. His subject was "Some Pitfalls in the Care of Cardiacs."

* * *

Dr. Paul M. Smith, Lake Crystal, enrolled in a four weeks' course in surgery at the Cook County Medical School in March.

* * *

Dr. O. M. Odlund, Granite Falls, will spend Tuesday and Friday afternoons at the Maynard Clinic, according to arrangements completed between the Maynard Clinic Board and members of the Granite Falls Clinic staff.

* * *

Dr. R. E. Risch has opened a new office building at 2915 Johnson St., N.E., Minneapolis. Having been in practice at 2854 Johnson St., N.E., since 1936, he now has an associate with him, **Dr. Paul V. Cummiskey,** Mankato. Dr. Cummiskey was graduated from the University of Minnesota. He practiced in Fresno, California and in Graceville, Minnesota, before joining Dr. Risch.

* * *

Dr. J. S. Blumenthal spoke to the dietitians at the Continuation Center, Friday, March 5, on "Diets in Allergic Diseases."

* * *

Dr. Merrill D. Chesler, Minneapolis, has announced the removal of his offices to 600 Physicians and Surgeons Building. His practice is limited to Plastic and Reconstructive Surgery.

* * *

The management of common medical problems involving the eyes, ears and upper respiratory tract were stressed at the course for general physicians at the Continuation Center. The course was under the direction of **Dr. L. R. Boies,** head of the department of ophthalmology and otolaryngology, and **Dr. Erling W. Hansen,** director of the division of ophthalmology.

* * *

Dr. Howard M. Frykman, Minneapolis, spoke on the topic "Office Proctology" at the monthly meeting of the Chippewa County Medical Society held at Chippewa Falls, Wisconsin, on March 9.

* * *

Dr. J. R. Balach has been named chairman for the business division for West Duluth for the American Red Cross Drive.

* * *

Dr. William B. Martin, Rochester, addressed the St. Louis County Medical Society. He spoke on atrio-septal defects.

* * *

Veterans administration officials have asserted emphatically that the Fort Snelling, St. Cloud, Fargo and Minot hospitals, among other VA hospitals, are on the national accredited list. The statement was made after the VA hospitals were omitted from the annual published listing. Phil Fordyce, VA director of public relations at Fort Snelling, telephoned Dr. Edwin Crosby, Chicago, director for the joint commission of accreditation, regarding the omission. Dr. Crosby explained that the VA hospitals are listed separately in the back of the accreditation book and were thus inadvertently overlooked. The explanation came after VA hospital doctors protested the omission.

* * *

Dr. C. G. Sheppard and **Dr. Elmer W. Lippmann,** Hutchinson, left by plane March 21 for Cleveland, where they attended the annual meeting of the American Academy of General Practice.

* * *

The Rochester state hospital announced in March that it had received a $31,000 grant from the Louis W. and Maud Hill Family foundation, Saint Paul, for a statewide two-year study on the prediction and control of Huntington's chorea. The study will begin July 1, under the direction of **John S. Pearson,** the hospital's chief clinical superintendent, and **Dr. Jorde A. Lazarte,** assistant superintendent. Faculty members of the University of Minnesota and the Mayo foundation will assist.

* * *

Dr. William P. Shepard, vice president in charge of health and welfare for the Metropolitan Life Insurance Company, will speak at the Middle States Public Health association meeting in the Hotel Saint Paul, June 2-4.

* * *

The alumni of the Cyrus Fishermen's College, of which **Dr. Herman Linde** is the dean, held its sixteenth annual banquet at Cyrus, on April 30. Dr. O. J. Jerde, St. Cloud State Teachers College, was the guest speaker.

Drs. Walter H. Ude, C. N. Borman and **Eugene E. Ahern,** Diplomates of the American Board of Radiology, announce the opening of enlarged new offices at 250 Medical Arts Building, Minneapolis. They will continue to maintain the offices at 701 LaSalle Building.

* * *

Dr. H. O. McPheeters, Minneapolis, recently spent the month of March in the Hawaiian Islands and reported a very fine vacation. While there he spoke before the Honolulu County Medical Society in Honolulu and the Maui County Medical Society on the Island of Maui, on the treatment of varicose veins.

* * *

Dr. Alan Challman, Minneapolis, has been selected by the Surgeon General, U. S. Army, for a thirty-day tour in the Far East, as a civilian Consultant in Psychiatry. He left April 6 and will return about the middle of this month. The tour includes visits to military installations in Japan, Korea, Okinawa, and Hawaii, for the purpose of improving the quality of medical care and instruction.

* * *

Dr. John W. Schumacher, Minneapolis, spoke to an adult education class at the Y.W.C.A. in Minneapolis, on "Common Misconception in Psychiatry" on March 15. Following the talk there was a question-and-answer period, at which time the various members asked questions about Psychiatry and its relationship to medicine.

* * *

Dr. Michael Danyluk, on April 1, 1954, became associated in the general practice of medicine at 1518 East Lake Street, Minneapolis, with **Dr. S. M. Lagaard.** On July 1, 1954, Dr. Danyluk will take over the entire practice since Dr. Lagaard will then specialize in the field of orthopedic surgery.

* * *

Dr. H. S. Diehl, dean of the medical sciences at the University of Minnesota, has been selected as one of three United States delegates to the annual assembly of the World Health Organization to be held in Geneva, Switzerland, May 4-22. Accompanied by Mrs. Diehl, Dean Diehl will fly to Geneva. The other two delegates to the assembly will be Dr. Leonard A. Scheele, United States surgeon general, and Dr. Chester S. Keefer, assistant secretary for health and medical affairs of the United States Department of Health, Education and Welfare.

* * *

Dr. and **Mrs. H. W. Meyerding,** Rochester, left March 29 for a two-month trip to South America. They will visit many of the places they toured in 1950. En route they attended the dinner of the International College of Surgeons in New York. Their first stop was Trinidad, then the Isle of Barbados, Bahai, Rio de Janeiro, Santos, Sao Paulo, Montevideo and Buenos Aires will be visited before returning to Santos and Sao Paulo where Dr. Meyerding will speak before the Brazilian and Argentine Orthopedic Society of which he is a member.

Dr. Albert V. Stoesser, Minneapolis, spoke on "Eczema and Urticaria" and on "Incidence and Treatment of Headaches Due to Allergy in Children" at the meeting of the American College of Allergists held in Miami Beach in April. He also took part in a round-table discussion on "Pitfalls in the Diagnosis and Management of Asthma."

* * *

Dr. and **Mrs. Titus C. Kreuzer,** Marshall, recently returned from a six weeks' vacation in Mexico. While in Mexico City Dr. Kreuzer attended the Pan American Congress of Otorhinolaryngology and Bronchoesophagology. They also visited Cuernavaca and Guadalajara. Dr. Kreuzer had previously become acquainted with Drs. Luis Martinez, Jr. and Jose Sanchez Cortes, heads of the departments of Ophthalmology and Otorhinolaryngology of the Guadalajara University School of Medicine. They requested Dr. Kreuzer to demonstrate his bloodless tonsillectomy. He performed six tonsillectomies before the Academy of Ophthalmology and Otorhinolaryngology and for ten days instructed the residents in the technique.

* * *

Dr. Owen H. Wangensteen, recognized as one of the world's outstanding leaders in the field of cancer surgery and the early diagnosis of cancer, addressed a dinner meeting in Winona on April 12, in observance of Cancer Crusade Month. His topic was "In This Great and Urgent Cause."

* * *

Dr. Russell L. Cox has recently been added to the staff of the Jackson Medical Center, Jackson. Dr. Cox is a radiologist and makes his home in Estherville, Iowa. He will be at the Medical Center in Jackson on Tuesdays and Fridays.

* * *

Drs. E. J. Baldes and **Jan Tillisch,** Rochester, attended the meeting of the Aero Medical association in Washington, D. C. Dr. Baldes is a member of the executive council and Dr. Tillisch is on the committee on aviation medical training.

* * *

Dr. M. B. Dockerty, Rochester, was on a tour of duty as resident consultant for the Armed Forces Institute of Pathology in Washington, D. C. He gave a demonstration and a lecture at the institute and also gave a demonstration at the Walter Reed General Hospital. During his stay in Washington Dr. Dockerty was the guest speaker at a meeting of former fellows of the Mayo Foundation. He spoke on New Developments at the Mayo Clinic.

* * *

On April 1, 1954, **Dr. J. P. Grahek,** Ely, purchased the partnership interest of **Dr. H. N. Sutherland** in the Shipman Hospital and Clinic. Simultaneously Dr. Grahek announced that two doctors have accepted positions with the hospital staff. It is anticipated that two more doctors will join the staff about July 1, bringing the total to five, Dr. Grahek stated. First of the new staff members, is Dr.

Frederick Colosey, Hartford, Connecticut. He received his pre-medical training at Trinity College in Hartford and then continued his training at Temple University in Philadelphia, where he received his medical degree. He served his internship in Frankfort Hospital in Philadelphia. The second new staff member is **Dr. Edward W. Ciriacy,** Philadelphia, Pennsylvania, who also received his medical degree from Temple University. He later completed a post-graduate course in surgery techniques and procedures at Frankfort and Temple Hospitals. Following his internship at Frankfort Hospital, he served on the staff of the Chestnut Hill Hospital which also is located in Philadelphia.

* * *

Dr. William A. Jordan, Minnesota Department of Health, spoke on the new fluoride treatment for the prevention of tooth decay and showed pictures to illustrate this work at the Parent Teachers Association meeting in Lafayette in March.

* * *

Research in the field of heart trouble was outlined to members of the Exchange Club at their weekly meeting in Hotel Saint Paul by **Dr. Ivan G. Baronofsky,** associate professor of surgery at the University of Minnesota. Dr. Baronofsky, also director of post-graduate surgical education at Ancker Hospital, reviewed what has been done to date on the problem of heart disease and latest surgical technique.

* * *

Dr. Ralph E. Smith, Department of Medicine at the Veterans and University Hospitals, Minneapolis, was the guest consultant discussing valvular heart disease at the March meeting of the McLeod County Medical Society in Glencoe.

* * *

Dr. Arthur N. Antonow has joined the staff of the East Range Clinic as obstetrician and gynecologist. He and his family have moved to Virginia from Highland Park, Illinois, where he was associated with Dr. A. F. Lash in the practice of obstetrics and gynecology. He was trained at the Cook County Hospital and Chicago Maternity Center and was also a member of the staff at Michael Reese Hospital in Chicago.

* * *

Dr. Robert W. Bachmeyer, Canton, Ohio, hospital administrator, is the choice of St. Barnabas hospital board to succeed **Dr. Karl S. Klicka,** who has resigned to become administrator of Presbyterian Hospital, Chicago. Dr. Bachmeyer has been administrator of Aultman Hospital in Canton since 1947. He served his residency in hospital administration at St. Luke's Hospital, New York, and then was assistant director at the Hospital for Special Surgery, New York, until 1942, when he entered military work with the United States public health service. Following his discharge from the army, he became assistant director of Children's Hospital in Boston, before going to Aultman.

Thirty-four fellows, including twelve from foreign countries, began studies with the Mayo Foundation, Rochester, for the spring quarter.

* * *

Dr. J. Burns Amberson, New York, world authority on chest diseases, delivered the annual John W. Bell tuberculosis lecture in Minneapolis April 5. **Dr. John H. Moe,** Hopkins, president of the Hennepin County Medical Society, presided over the meeting. The John W. Bell lecture is co-sponsored by the Hennepin County Medical Society and the Hennepin County Tuberculosis Association. The Bell lecture brings outstanding tuberculosis authorities to Hennepin County.

* * *

Dr. William F. Maloney, acting assistant dean of the Medical School at the University of Minnesota, was guest consultant at the first of two scheduled clinical conferences held for the medical staff of the Itasca County Memorial Hospital in Grand Rapids on April 14. Dr. Maloney presented case histories of patients with heart diseases. He also discussed with the medical staff some of the recent techniques and methods being employed in the diagnosis and treatment of cardiac disorders.

* * *

Lieutenant (jg) John E. Indihar, son of **Dr.** and **Mrs. J. E. Indihar,** Chisholm, has been assigned to the Oakland, California, Naval Supply Center. The twenty-eight-year-old physician was called to active duty in the Navy last September. He had been serving at the Naval Medical Center, Bethesda, Maryland, until his assignment to Oakland. Dr. Indihar was engaged in general practice in Ely and Virginia before he entered the service.

* * *

Dr. Harold J. Walder, Duluth clinic urologist, spoke on the increase in certain types of cancer in the Duluth area at the noon meeting of the Rotary Club, April 8.

* * *

Dr. Clyde A. Undine, Minneapolis, attended the National convention of the American College of Physicians held in Chicago, April 5-9.

* * *

Dr. Paul Winchell, department of medicine at the Variety Club Heart Hospital, was guest consultant at the first of two clinical conferences held for the medical staff of St. Mary's Hospital in Detroit Lakes, on April 14. Dr. Winchell is doing research on various disease conditions of the heart and is well qualified to evaluate some of the techniques and methods now being used in diagnosis and treatment of heart diseases.

* * *

Minneapolis Veterans Administration Hospital will take part in a co-operative research program with other VA hospitals to provide more accurate standards for diagnosing and treating heart and lung diseases. **Dr. John A. Seaberg,** hospital manager, said measurement of heart and lung functions has been carried on at the hospital for several years. Studies at the Minneapolis hospital are being conducted by **Dr. Ralph Smith**, cardiology service, and **Dr. Frank Martin**, tuberculosis service.

* * *

Dr. Rudi Schmid, University of Minnesota instructor in medicine, has been awarded a special $6,000 research fellowship by the National Institutes of Health. The one-year fellowship begins July 1. Dr. Schmid will study at Columbia University. Dr. Schmid, a native of Switzerland, spent his residency at University Hospitals in 1948. He has been an instructor of internal medicine since 1952.

* * *

Dr. Nicholas H. Zeller has joined the staff of the Worthington Clinic as a specialist in internal medicine. Dr. Zeller comes to Worthington from the Veterans Administration Hospital in Saint Louis, Missouri, where he held the position of assistant chief of medicine. He graduated from the University of Minnesota in 1946 and since that time he has been taking specialty training in internal medicine at the Saint Louis Hospital.

* * *

Dr. William J. Muesing joined the Seifert Clinic in New Ulm early in April. He recently completed a four-year residency in general surgery with the Youngstown, Ohio, Hospital Association. Dr. Muesing attended St. Olaf College and the University of Minnesota, graduating from the University Medical School in 1946. He took his internship at the San Diego, California, Naval Hospital.

* * *

Dr. Alan Hodges, head of the Southern Minnesota Mental Health Clinic at Albert Lea, discussed his work with the mentally retarded at the meeting of the Austin Association for the Mentally Retarded in April. In an informal question-answer session, Dr. Hodges outlined the services offered and the mental illnesses treated at the clinic.

MINNESOTA BLUE SHIELD-BLUE CROSS

Already, in the February monthly report of Blue Shield affairs, it is evident that more of the Blue Shield subscriber's dollar is being spent for claims. This was the Board of Directors' purpose in increasing the benefits or fees which became effective for services rendered subscribers on and after January 1, 1954. Up to the present time, a significant proportion of the claims processed are for services rendered prior to the first of this year. Consequently, the full effect of the increased fees is not readily predictable even though the trend of the increase in claims cost is apparent.

During 1953, 76.8 per cent of the cash earned from subscribers was devoted to the cost of claims. This was a distinct increase over 1952 when 70.2 per cent of this income was disbursed for claims. For January of this year, this percentage increased to 77.2 and again in February it increased to 77.9. Even though these increases are slight, it is assumed they indicate a trend. The latter figure is more impressive considering the fact that it is a short month and, also, since a not inconsiderable proportion of the claims involved services uninfluenced by the increases of fees which became effective the first of this year.

Other features of the report for February emphasize the fact that while the trends shown are apparent, the time has been too short to make broad conclusions. For instance, the proportions of claims involving surgery and obstetrics are practically the same as last year, whereas, there is a definite increase in claims involving medical care, x-rays and anesthesia. If the present trend continues throughout the year, medical care services will experience about a ten per cent increase in general and emergency medical care services almost a 50 per cent increase. Based on data in the February report, claims for anesthesia may show a final ten per cent increase and x-ray claims about five per cent.

Increased cost of claims is important in its relationship to the organization's reserves for future medical and surgical care and contingencies. In fact, as soon as such reserve funds began to approach the level which has been recommended for soundness and security, more money was allocated by the Board of Directors to increased benefits. It was the result of this policy that many of the fees were increased the first of January, 1954. In the light of these facts, it is important that while for the year 1953, 14.1 per cent of gross income was transferred to unassigned surplus to meet contingencies, only 10.7 per cent has been allocated to such reserves during the first two months of 1954. That this percentage is likely to decrease throughout the year is evident from the fact that in February it was only 9.2 per cent.

From the facts presented, it is obvious that the increased benefits or fees are already requiring an increase in the percentage of income spent from medical-surgical-obstetrical claims, and that a decreasing percentage is available for reserves. However, these developments are in keeping with the non-profit motive of Blue Shield and also with the Board of Directors' policy to return as much of the income to subscribers in the form of benefits for various types of doctors' services as is financially sound.

HOSPITAL NEWS

Following is a list of the officers of the staff of Hibbing General Hospital and department heads for the year 1954:

Officers	
Chief of Staff	Dr. B. F. Flynn
Vice president	Dr. J. L. Arko
Secretary	Dr. G. Doxsee
Department Heads	
Medicine	Dr. W. G. Tomhave
Surgery	Dr. C. Jacobson
Otolaryngology	Dr. A. Sinamark
Ophthalmology	Dr. T. R. Schweiger
Contagion	Dr. C. A. Tingdale
Pediatrics	Dr. C. N. Harris
Radiology	Dr. B. Halper
Pathology	Dr. H. R. Irwin
Obstetrics	Dr. T. A. Estrem
Physiotherapy	Dr. S. Lipinski

BOOK REVIEWS

Books listed here become the property of the Ramsey, Hennepin and St. Louis County Medical Libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

TUBERCULOSIS IN CHILDHOOD AND ADOLESCENCE. By F. J. Bentley, M.D., F.R.C.P., D.P.H., Senior Physician, and S. Grzybowski, M.D., M.R.C.P., Senior Registrar, High Wood Hospital for Children, Brentwood, Essex; and B. Benjamin, B.Sc., F.I.A., formerly Statistician, London County Council. Preface by Sir Robert Young, C.B.E., M.D., F.R.C.P. Foreword by Wilfrid Sheldon, C.V.O., M.D., F.R.C.P. 272 pages. Illus. Price $5.00. London: National Association for Prevention of Tuberculosis, 1954.

This must surely be the first major project of clinical research arising from the National Health Service since the new scheme for decentralized research was set out in 1953. In point of fact, the present study was commenced shortly after the National Health Service was inaugurated, although final arrangements for decentralized research have only recently been promulgated.

The work is based on an experience of over 1,000 children treated in sanatorium and followed up for an average period of six years. A special investigation into the clinical and pathological details surrounding the deaths from tuberculosis of 100 unselected London children is also included, and this reveals the extent to which death from this disease in childhood may be preventable.

The practical management of tuberculosis in children has so far presented a confused and uncertain picture and this has probably arisen from an acceptance of the pattern of the disease as it has been so fully studied and understood in adults. It is the authors' contention that, apart from those rare instances of the adult type of the disease, pulmonary tuberculosis in childhood presents an entirely different clinical picture. Data are provided, for example, which demonstrate that the extent of the radiological shadows in primary disease is often of very little prognostic significance.

The various manifestations of the disease in childhood and adolescence are considered from the aspect of incidence, diagnosis, prognosis and treatment in such a way that the publication can be used as a text-book.

An original picture of the possible connections between primary tuberculosis and the adult type of disease is outlined in a chapter on pathogenesis. Although some of these views may be found controversial, they should certainly stimulate further thought and research on this important subject which, for so long, has been dominated by theories formulated in the early years of the present century.

As Dr. Sheldon states in his Foreword, High Wood Hospital—the largest hospital for pulmonary tuberculosis in children in the country—was an ideal field for observation. In addition to the prolonged period of residential treatment, over 90 per cent of the cases were followed up for many years. No other centre could have supplied so much information and particularly is this the case in the section dealing with chronic pulmonary tuberculosis (the adult type of the disease)—a section described by Dr. Sheldon as unique.

The authors' findings demonstrate that our methods of dealing with the disease in children have become unsatisfactory and call for an overhaul of both clinical and administrative arrangements.

The book will also be of great value in those parts of the world where the main battle against tuberculosis has still to be fought, as the fundamental pattern of tuberculosis shows striking similarities although its tempo may vary from country to country.

RECENT ADVANCES IN CARDIOVASCULAR PHYSIOLOGY AND SURGERY. A symposium presented by the Minnesota Heart Association and the University of Minnesota at the University of Minnesota in September, 1953. Edited by Grace M. Roth, Ph.D., Rochester, Minnesota, Chairman of the Committee for the Symposium. 132 Pages. Illus. Paper binding, $1.00. Saint Paul: Minnesota Heart Association, 532 Endicott-on-Fourth, 1954.

This symposium brings together the important contributions of a representative group of investigators from various parts of the United States, Canada, and Europe, and was designed to include discussion of the various aspects of new knowledge in cardiovascular physiology and surgery.

Subjects covered in the three-day symposium are: Heart Muscle Contraction, Regulation of the Circulation, Measurements of Pressure and Flow, Differential Diagnosis of Various Defects by Physiologic Means, Recent Advances in Surgical Treatment of Heart Disease. The George Fahr Lecture on the Physiology of Congestive Failure of the Circulation, presented at an evening session, adds to the comprehensive scope of the presentation.

Contributors to the symposium include:

Wilfried F. H. M. Mommaerts, Western Reserve University School of Medicine, Cleveland; Olle Snellman, University of Uppsala, Uppsala, Sweden; Torgny Sjostrand, Karolinska Hospital, Stockholm, Sweden; Otto H. Gauer, Aero Medical Laboratory, Wright Air Development Center, Dayton. Robert F. Rushmer, University of Washington School of Medicine, Seattle; Richard W. Stow, Ohio State University College of Medicine, Columbus; Erik Wetterer, University of Munich, Western Germany; Earl H. Wood, Mayo Foundation, Rochester; C. W. Sheppard, Oak Ridge National Laboratory, Oak Ridge; John W. Remington, Medical College of Georgia, Augusta; Homer R. Warner, University of Utah College of Medicine, Salt Lake City; Lewis Dexter, Harvard University Medical School, Boston; H. J. S. Swan, Mayo Foundation, Rochester; Charles T. Dotter, University of Oregon Medical School, Portland; Robert P. Glover, Hahnemann Medical College and Hospital, Philadelphia; John H. Gibbon, Jefferson Medical College, Philadelphia; W. C. Bigelow, University of Toronto, Toronto, Canada; Henry Swan, University of Colorado School of Medicine, Denver; Willis J. Potts, Northwestern University Medical School, Chicago; Dwight F. Harken, Harvard University Medical School, Boston; William F. Hamilton, Medical College of Georgia, Augusta.

This is a valuable addition to any physician's or surgeon's library and should be of particular interest to those specializing in cardiology.

Minnesota State Medical Association Roster for 1954

PROBLEMS AND OBLIGATIONS OF ORGANIZED MEDICINE

O. J. CAMPBELL, M.D.
Minneapolis, Minnesota

I HAVE BEEN asked to discuss some aspects of organized medicine, particularly its problems, its obligations and its relationship to teaching institutions. I suspect that I have been asked to do this because my background should enable me in some measure to bridge the gap in point of view between those in private practice and those who are full-time teachers. While this task has not been easy, I have found it a pleasure because it has offered an opportunity to express some deep convictions.

The future of medicine, I believe, is inseparably bound to a wise, healthy, farseeing, over-all organization which considers the rights and interests of all branches of medicine and which is at once receptive to change, resistant to exploitation, a stimulant to scientific progress and the better utilization of that progress, a monitor of the competency and behavior of its membership, a trusted and respected interpreter of medical thought to the public and all this for the betterment of medical care. The realization of this is a larger order which we have not yet fully achieved but it is a goal toward which we must direct our thoughts and energies.

I am sure that the great majority of us believes in a type of medical practice which is compatible with a free enterprise system. I am sure that the great majority is friendly to the American Medical Association which, as you know, is only the aggregate of all state associations which in turn are the aggregate of all county associations. Trained as you are to challenge existing practices and ideas in the hope of improving them, it would not be unusual if a few entertained ideas which are quite at variance with the views of most of us. If there are such, they are considerate to the wishes of the majority and reasonable enough to know that were they in different positions, active practice for example, they might think differently.

I would like to express some of my own ideas concerning our problems and obligations as a medical organization, which ideas I have reason to believe are not too far removed from those held by the many able men who are giving their time, thought and energies to medicine's needs, who can visualize our goal, and who hold no illusions regarding the pitfalls and road blocks to be overcome.

Our most serious problem, and I should add "in my opinion," for I have rarely heard this thought expressed, is to resist the forces which threaten to divide us. Our recent struggle to escape compulsory health insurance, which was actually a closer call than many realize, indicates what the socializers would do to the practice of medicine were we to become split into factions.

Segmentation and division along lines of special interests assume a constantly increasing menace. Specialization in which whole groups with little knowledge of, or interest in, the problems of other groups fosters the illusion of self-sufficiency.

The general practitioners, who make up well over one-half of all practicing physicians and without whom we could not, for the foreseeable future, serve the American public, create a special problem. Today, the general practitioner feels threatened, suffers from loss of prestige and a sense of insecurity. Especially this is true in the cities where he is in competition with the specialist

---

Address delivered before the Faculty and Alumni Association, University of Minnesota, November, 1953.

and where everything he does is measured in terms of specialist performance. In rural areas, he fares better and in most cases measures up to the finest traditions of "the family doctor."

Today the general practitioner has his own organization and operates it from the praiseworthy standpoint of education of its membership and from the understandable viewpoint of self-protection. How tragic for medicine if the general practitioners and specialists would engage in a bitter competition for public favor!

There is urgent need today for organized medicine to summon all of its divergent elements and to define and spell out a reasonable relationship, especially between general practitioners and specialists.

To illustrate, the American College of Surgeons has declared it a breach of ethics for a surgeon to use a referring general practitioner as an assistant. Granting that on occasions such assistance may be but a subterfuge for a split fee and, granting that the general practitioner has no vested interest in his patient, he, nevertheless, often by being the family doctor, holds a trusteeship toward his patients' health, which would be poorly served were he forced off the case when surgery is involved. Most of us who are members and strong supporters of the College believe this to be wrong, believe it will discourage requests for consultation and reference of cases and will serve to isolate general practitioners into a resentful and dissident group.

The principle which I wish to emphasize is that questions as basic as that of ethics and that of all-important relationships is a matter to be settled by organized medicine as a whole and not by a special group, no matter how sincere the motives or how great the qualifications to advise.

Thinking further along this line, there is urgent need for organized medicine to gather its resources and courage and to clean up unwholesome and immoral practices within the confines of its own doors. It is, in my opinion, to our everlasting discredit that we did not stop rebates for optical goods and all other forms of rebates until forced to do so by governmental action.

The American College of Surgeons has undertaken a crusade against fee-splitting, ghost surgery, and excessive fees, all reprehensible practices which should have been eliminated long ago. It should not have been necessary for the college to do this, and it is particularly unfortunate that they should have had so little confidence in the help that organized medicine would give them that they took their crusade out of medicine's lap and put it before the public. Again, most of us who will be glad to support any campaign to eradicate such practices, believe that the first step should have been to seek an agreement regarding a definition of fee splitting. All branches of medicine should have participated in reaching such an agreement. After full agreement, the whole-hearted co-operation of the American Medical Association should have been sought and should have been given.

Articles such as appeared in a recent issue of Colliers might not then be so disturbing to the public, so damaging to the confidence we seek to inspire, and so misleading about the extent of the evils described. The article did, indeed, admit that the majority of practitioners do not indulge in such misconduct, but it says so in fine print, figuratively speaking.

Closely allied to the eradication of gross and blatant evils is medicine's obligation to examine and to pass judgment upon the quality of service rendered by its members. Up to this time, it has been difficult if not impossible to do this. It has always been easier to avoid accepting a man into organized medicine if there is reason to doubt his worthiness than to extrude him after he has become a member. The courts have made it so difficult to discipline a member that his offense must be great before he can be expelled. Court action which is pending in Minnesota may be helpful in defining our rights in legal terms.

As many of you know, the Two Harbors Co-operative medical group is suing certain members of the St. Louis County Medical Society for the large sum of over $300,000, claiming conspiracy. Out of this suit, it is to be hoped the rights of medicine will be so clearly established that we may be able to limit our organization to men who foster the type of medicine in which we believe and who maintain the highest ethical and scientific standards.

A study of the problem of monitoring the quality and excellence of practice of the individual member leads inevitably to the conclusion that the place to regulate is at the hospital-staff level. I believe that the recently promulgated rules applying to staff organization and staff obligations which have been issued by the joint Accrediting Committee and which, as you know, require a critical review of every patient admitted to a hospital, clearly indicate such a viewpoint. These edicts are creating a furor, not only because of the added time and responsibility they demand, but more importantly because they require an adjustment in our thinking. Accustomed to freedom of thought and action in the practice of medicine, it is hard for us to accept the idea of supervision by our confreres. However, it is, in my opinion, an important move toward improvement of the quality of service which the public receives. With certain necessary modifications, some of the inconveniences may be eased. The hot breath of censure will most certainly put wings on the feet of the laggard and fear in the heart of the dishonest.

Organized medicine is very much opposed to federal aid to the medical schools. Perhaps some of you may not agree with this position, but you will respect the motives. We feel that support will eventually lead to control, and we believe it to be to the best interests of medicine and of the public to keep our medical schools free of governmental dictation or control of any kind or degree.

The American Medical Association, through a foundation established for the purpose, is attempting to raise substantial funds from its own membership to aid medical colleges. They have fostered other foundations and agencies also seeking funds for our schools. Admittedly, at this time, the moneys which have been raised fall short of the needs, but with more time the accomplishment will be greater. This country which raises so much money for privately endowed colleges will not desert its medical schools.

To stay strong, medicine must remain sensitive and responsive to public needs and demands. Never again will we withdraw from and neglect our public relations. Review but briefly our response to the public's reasonable demand: All over the country, implementing the request of the American Medical Association, county medical societies have established grievance committees to which any person who feels that he has been misused by a member of our profession may bring his complaint and receive satisfaction through explanation or redress.

We have made it possible for anyone to secure a physician within a reasonable time. Different mechanisms operating in various ways are employed over the whole country to assure availability of medical care to the public.

We have recognized the public's complaint of high costs of medical care, and have fostered and promoted the sale of voluntary prepayment forms of insurance, such as the Blue Shield plans, and also the direct and indirect encouragement of the sale of commercial contracts covering surgical and medical expenses.

Today, according to testimony of major insurance companies at hearings before a House Committee, 91,000,000 men, women, and children are covered by hospital insurance, 73,000,000 have surgical-expense coverage, and 36,000,000 are protected against medical expense.

Policies covering catastrophic illness are making their appearance. Two years ago California initiated this in conjunction with their standard Blue Shield policies; others, including private insurance companies, are following. Edmund B. Whittaker, vice-president of Prudential Insurance Company, estimates that already one million people are covered by this form of policy.

The voluntary insurance method of attacking the problem of high costs will never satisfy those who believe that people have a divine right to good health without personal responsibilities for it. It is their contention that under a voluntary prepayment insurance system, man cannot afford his medical care along with food, clothing, shelter and recreation. They completely abandon the spirit of independence, self reliance and free enterprise in favor of governmental paternalism, socialism or some of the other "isms."

Furthermore, I believe that, to earn the respect to which it is entitled, organized medicine has the duty of fostering within its membership a stronger sense of obligation toward citizenship and toward civic responsibility. Perhaps it is because our old tradition taught us to be self-effacing as far as the public is concerned that doctors feel detached from civic activities. Regardless of the cause, it is harmful to us to shirk either the financial demands of our communities or the demands they may make upon our time and energies. When other groups are doing a good job, can we afford to do otherwise?

In the minds of many, medicine should shun politics. What is politics but the business of operating our civilization? We can no more shun politics than we can waste our vote by boycotting the polls.

In this phase, I have followed a rather philosophical, and, some may believe, unrealistic approach. I am quite ready to admit that organized medicine has made many mistakes and will unfortunately make more. I would not have you believe that I consider our need for unity transcends the right of any individual or any group to disagree, to debate and to dissent. You have only to attend a meeting of the House of Delegates to hear very vocal dissension. I ask only that these differences and debates be held within our own portals, and that when the vote is cast the will of the majority shall not only prevail but be freely adopted.

I wish to reiterate my belief that medicine shares in the unrest and the uncertainty afflicting this country and the entire world, that medicine as we would have it is still in danger and that, just as the free world needs a strong America, so free medicine needs a strong American Medical Association.

I would rather skip the next phase but to do so would be to shun an obligation to help smooth out a totally unnecessary feeling of unfriendliness which seems to have crept between our medical school and some of the doctors in our state. It is hard to evaluate this feeling, its origin, its extent or its intensity, but perhaps it is only necessary to know that it exists in order to move to correct it.

Last year, Dr. Charles Sheppard of Hutchinson, speaker of the House of Delegates of the Minnesota State Medical Association, ably represented the point of view of the rural general practitioner and the views he expressed must be considered as held by many of the men in rural practice. The faculty may believe that many of the direct and implied criticisms were unjust, some of the suggestions impractical or outweighed by other considerations. Nevertheless, right or wrong, just or unjust, it was good that he expressed his views.

I am somewhat mollified to think that at the state level our relationship with organized medicine has been excellent. Has not Dr. H. S. Diehl been a faithful attendant at council meetings, given hours of study on important committee assignments and has he not done as much or more on a National level? As a matter of fact, many of our members, including some heads of departments, have worked for organized medicine: Drs. Howard, Spink, Keys, Bieter, Wangensteen, McQuarrie, to mention only a few of them.

Finally, I reflect on the fact that our school cannot grow greater in an atmosphere of professional suspicion and disapproval. Especially this is true when the financial support comes for the most part from taxes appropriated by the state legislature, and our clinical material from the bailiwicks of both friends and critics. I now, therefore, try to evaluate what part of our critics' complaints is valid and how much of it is based on misinformation or misunderstanding.

Let me revert to my role as friendly critic and advisor and attempt to assay the situation in the hope that there may be an easy correction to whatever valid basis of ill feeling may be found to exist.

I believe that the medical school may feel most secure in its relations with the specialists in Minnesota. Within this group criticism and ill feeling are least likely to exist; rather the faculty is held in highest esteem and is called upon frequently for consultation and advice.

Within the Twin Cities, however, there is a tiny fear, a smoldering apprehension, that in years to come, with its source of teaching material from rural areas drying up, a gradual emphasis in private practice among the faculty will result in a large private clinic maintained by taxes and in competition with the private physician.

Let me hasten to add that I am not aware of antagonism to private practice on the part of full-time men when done on a limited basis. The doctors, proud of and ambitious for their medical school, know that we cannot keep good men as heads of departments if they are limited to the same remuneration as a professor of Romance Languages. It is true that those of us who lose private patients to the University actually contribute more to the support of the medical school than do laymen who merely pay taxes. We do not object to the situation as it now exists, but would certainly not willingly accept the presence of a large private clinic. But why worry about something that does not exist?

There is far less ill-feeling among general practitioners in cities than in urban areas. In the matter of sampling, I have found very little antagonism. A general practitioner friend of mine who is very active in the Academy of General

Practice in Hennepin County told me only a week ago that since Dr. Howard had assumed his position, relations between the general practitioner of his area and the medical school had improved greatly.

We come finally to the rural general practitioner, where our real problems lie. These men have been for years feeders of the University Hospital. These are the men who have been most seriously handicapped and frustrated by failure to obtain assistants and replacements in their areas. These men also are allergic to the attractions of specialization for the younger men. Happy in their work and in their positions in their communities, they cannot understand why new graduates in medicine should hesitate to enter general practice in the "country." To add to their frustration, they cannot obtain nurses or even the right to train the nurses needed to operate at their hospitals. This may explain why at times they may appear unreasonable.

I am convinced that our medical faculty does nothing deliberately to discourage our graduates from becoming general practitioners. Our offense, if there is an offense, is one of omission and not commission. In other words, the only question is as to whether we as a faculty are doing all we can to encourage graduates up to the point where the needs of the state are met. After that we have no obligation to influence. Some of us may feel we have no right to attempt to influence.

I believe that we can obtain enough information pertaining to student motivation to clear us of any suspicion of influencing the student toward specialization. I believe also that such information should be gathered, analyzed, and transmitted to the medical profession of the state. For the sake of harmony, we should defend ourselves vigorously in this respect.

I do not believe that medicine would want its medical schools staffed exclusively by teachers whose sole aim and qualification is to turn out good practitioners of medicine. It is good that some teachers find their greatest satisfaction in the superb training of men who are thereby made capable of supplanting or excelling them and that through this and through research they make their greatest contributions to medicine and mankind. We ask only that they not neglect the requirements of providing the needed practicing physicians for the people whose taxes support our school.

We come now to what I consider the only justification for the resentful attitude of these men. Over a period of years in which they have been sending their low income or indigent patients to the University Hospital, a number of irritating incidents have occurred either to them individually or to a confrere whose experience they embrace as their own. A report is not received. It is very tardy. It is sketchy. It is enormously detailed but not summarized. A patient referred to the hospital is sent back without treatment and without explanation. The patient hears or thinks he has heard remarks criticizing the referring doctor. These and a host of other complaints are offered by the rural doctor to explain his reluctance to send his patient to the University Hospital. Add to this the fact that local commissioners charged with the financial responsibilities of the patient's care have found that it is less expensive to use the new hospital in the community than to use the University Hospital, and the patient would rather stay home within easy reach of his family. You will then understand why clinical material is becoming harder to get.

May I offer a suggestion? Complaints on the part of referring doctors are far less common when the patient is a private patient referred to a specific member of the staff. This is because the staff man immediately establishes a consultant relationship with the referring doctor.

Why not the same attitude toward every patient and every referring doctor? Let the code of ethics of the American Medical Association pertaining to consultations and referrals apply in these cases insofar as it is possible to apply it. This simple adjustment in thinking and the mechanics to operate it are in my opinion all that is needed to start our hospital and staff toward a fine relationship with the doctors of the state who will then see that the medical school does not suffer for want of clinical material.

One other suggestion which I have already made to Dr. Diehl: the University Hospital and the Medical School should have a professional relations man, who will visit the county medical societies, and even the doctors' offices to acquaint the

(Continued on Page 414)

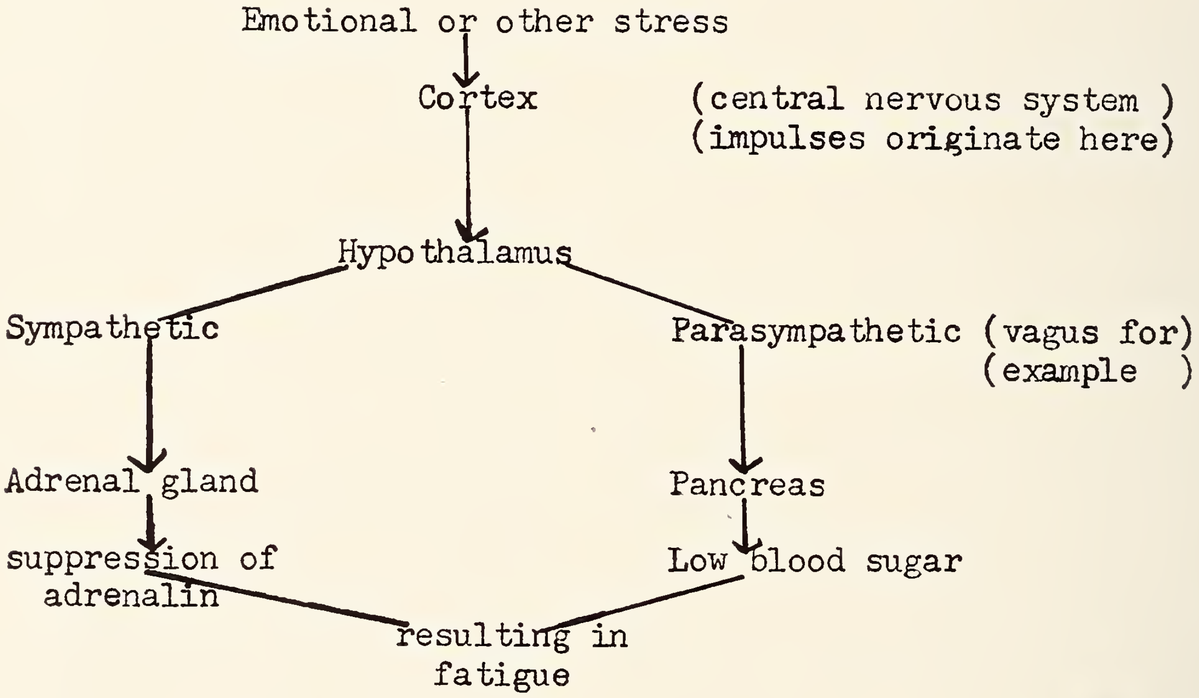
NEUROGENETIC INHIBITORS FOR FUNCTIONAL DISORDERS

NORMAN E. RUD, M.D.
Minneapolis, Minnesota

Whether or not an illness is purely a functional disturbance or an organic lesion, the disease pattern is always modified by emotional factors. Evidence today points out that the autonomic nervous system is the main link in transforming emotional stimuli into somatic responses. Corroborative evidence is provided by the fact that the influence of emotional stress is particularly marked where a disease mainly affects functions under autonomic control, and by the fact that great benefit results from treatment with drugs acting on the autonomic nervous system.

Basis of Therapy

In view of our experience with a large number of patients presenting functional ills, we agree with the present-day theory that autonomic imbalance is largely responsible for the development of such conditions. The following diagram explains briefly how the various nerve pathways play a mechanistic role in the development of such symptoms.



The above sketch shows the result of emotional impulses on two particular organs leading to the symptom—fatigue. It must be pointed out that every organ is innervated by these pathways and that any change in the number of nerve impulses will produce a variation in organ function. These changes are manifested by such symptoms as sweating, palpitation, diarrhea, constipation, et cetera.

Treatment

It is often difficult to pin-point the exact nature of functional gastrointestinal symptoms or that of any functional ill for that matter. Oftentimes, a particular individual who has worked himself into a key job in a large organization and who may be under constant tension and pressure develops symptoms of gastrointestinal distress because economically he knows he cannot quit his job for which he has worked so hard and long, and yet truthfully realizes his inadequacies (Case 2). Medication in this type of individual is difficult. One cannot rightfully employ large doses of barbiturates because, actually, this will not cure him and, in addition, will produce drowsiness and slowing of his thinking which will make the handling of his tasks even more difficult.

Most physicians realize that one cannot state a fast and hard rule which will cover medications for every patient. It is necessary to remember that every patient is an individual and that for every individual a specific regime should be organized which will be most effective for him. For example, in a proven case of duodenal ulcer (in which tension state is present), immediate relief is not always obtained with such standard accepted anticholinergic drugs (Banthine®, Pro-Banthine®, Prantal®, Antrenyl®), in addition to antacids and a proper diet. We have found that the addition of a complete autonomic stabilizer (1 tablet b.i.d., or t.i.d) may often be sufficient to make therapy successful. When gastrointestinal disease exists in older individuals—during the climacteric phase—one may often find that the addition of estrogens or androgens may be desired in order to convert ineffective therapy into beneficial therapy. One must be careful, however, not to employ drugs which may be contraindicated or harmful.

From the above diagram, one quickly sees that if the excessive impulses set forth by the central nervous system, and both the sympathetic and parasympathetic activity can be reduced, autonomic imbalance can thus be restored and symptomatic relief eventually achieved. Basic pharmacologic studies by Rothlin[5] demonstrated that drugs inhibiting either the parasympathetic or sympathetic nervous system could be given together without balancing out their effect. In other words, ergotamine tartrate continued to inhibit sympathetic impulses, and belladonna alkaloids continued to inhibit parasympathetic impulses even though administered together. Addition of phenobarbital did not diminish activity of any of the three drugs. Administration of this combination restores autonomic balance because it acts on all three nervous pathways involved in the development of functional symptoms. Karnosh and Zucker[2] have previously suggested that "probably the best medication for all neurovegetative disorders is a combination of bellafoline (vagal sedative), ergotamine tartrate (sympathetic sedative), and phenobarbital (cerebral sedative)." Recent papers[1,3,4,6] indicate the therapeutic trend toward the control of such conditions by means of controlling autonomic activity.

Case Histories

The following case histories demonstrate our results with this agent.*

Case 1.—W. S., a white, forty-seven-year-old milkman, presented himself with a typical history of duodenal ulcer of six weeks' duration. He complained of severe epigastric pain, relieved by food, but which developed two to three hours after eating. He had severe heartburn and spasm. There was no history of previous illness, but the patient had been operated on several years before for an inflamed appendix. Family and marital history were negative.

Physical examination revealed no abnormalities. The man was of normal weight for his height. Upon palpitation the epigastric area was found to be tender. A laboratory examination was completely negative. This included a complete blood chemistry, sedimentation rate, etc. The x-ray studies revealed a typical, small but active duodenal ulcer.

He was placed on a typical ulcer regime, starting out with milk for a few days and gradually increasing non-acid forming foods. He was given antacids and anticholinergic agents. At the same time he went on vacation in order to completely follow the regime and get needed rest.

He returned after one week on the ulcer regime with very little improvement in his symptoms. The pain was as severe as previously. Interestingly enough he complained of severe fatigue and lassitude, although he was not working, and was supposedly on a restful vacation. The above regime was continued but in addition he was prescribed one tablet t.i.d.-a.c., of Bellergal (complete autonomic stabilizer), and one b.i.d.-a.c., of therapeutic B-Complex capsules. He was seen three days later and appeared completely relieved of all symptoms. He stated he no longer felt so tired and was able to enjoy his vacation, and was completely free of his gastric symptoms. He has been on this regime for over a year with no further complaints. X-ray studies show healing of the ulcer crater.

The above case history shows the effectiveness of the addition of a complete neurovegetative sedative in the treatment of duodenal ulcer. This organic lesion often has with it an emotional overlay which may prevent prompt healing. The symptom of fatigue is typical of a functional disorder and as previously discussed will only improve with restoration of autonomic balance.

Case 2.—This thirty-seven-year-old male executive who presented a history of severe atypical pain in the epigastrium region and left upper quadrant of the abdomen, of one and one-half years' duration. This individual assumed a great deal of responsibility in his executive capacity and he took his position and work most seriously. He attained this position at a young age which resulted in a feeling of insecurity for fear that he was unable to live up to the demands made on him.

He apparently had no family or marital problems and had had no history of previous illness. The physical examination was negative except that on palpitation there was tenderness in the epigastrium and upper left quadrant. Laboratory examination was entirely negative. Two complete sets of gastrointestinal series were made, as well as one gall-bladder x-ray study. All three of these were negative except that they revealed a spastic colon. This finding is entirely in keeping with the history of nervousness and feeling of insecurity due to his position. He was placed on a bland roughage diet and prescribed anticholinergic agent and sedatives (barbiturates), with no relief.

---

*Bellergal (Sandoz).

After several trials with a variety of drugs he was finally placed on one tablet t.i.d.-a.c. of Bellergal and 0.5 grams of Mephenesin t.i.d. He was seen two weeks later and had shown much improvement. The Bellergal was reduced to one tablet a.c. and 0.5 grams of Mephenesin b.i.d. He has been on this dosage for six months and has been completely relieved of his gastric pain and distress.

This case history is a typical example of a functional disorder. It is easier to diagnose, for the simple reason that the emotional cause of the symptoms are obvious upon discussion. There are two problems with such a patient, for besides being able to control the symptomatology, one must also help him to adjust to his environmental stresses. As previously discussed, the proper use of a complete autonomic sedative aids in producing symptomatic relief. By stopping the pains the patient naturally feels better and can begin to learn to adjust himself emotionally. In this particular instance the cause of his problems were discussed with him and after several sessions, he began to understand how his symptoms resulted from the stresses under which he was living. He was advised to try and get more relaxation, particularly out-door exercise, and to try and develop some interesting hobby in order to have something, other than his work, on his mind. Many of these executives fail to "leave their work in the office," and must be educated not to take it home with them. Under a modified regime this patient has continued to show marked improvement.

Conclusions

We have presented two examples of case histories which demonstrate a method of treating gastrointestinal disease of a functional or organic nature, or, in which a combination exists. We recommend a drug which contains sympathetic, parasympathetic and central inhibitors, for this particular combination appears to work more rapidly and appears to necessitate smaller doses than any drug previously used. Other adjuncts such as Mephenesin or hormones are employed as indicated. The emotional aspect of these conditions must be considered and adequate psychotherapy instituted in order to help the patient readjust himself to his environmental stresses.

PROBLEMS AND OBLIGATIONS OF ORGANIZED MEDICINE

(Continued from Page 411)

doctors with University problems and in turn to learn the doctors' problems and what the staff can do to help them.

It has been my very great pleasure and privilege to try to serve both organized medicine and the medical school of this state. I have tried to interpret to each the attitude of the other. There is no incompatibility. There is no clash of interests. There should be no friction.

I am sure that the physicians of this state are very proud of their school and wish to see it continue to climb in stature and recognition.

CHANGES IN BONE AFTER EXPOSURE TO ULTRASONIC ENERGY

NICHOLAS I. ARDAN, JR., M.D., JOSEPH M. JANES, M.D.,
and
J. F. HERRICK, Ph.D.
Rochester, Minnesota

INTEREST in the medical application of ultrasonic energy gained initial momentum in Germany, in 1932.[3] Since then, many widely varying conditions have been considered to be indications for ultrasonic therapy. In an effort to establish a basis for the clinical application of ultrasound, workers at this institution have studied various experimental aspects of this problem during the past six years. The outstanding conclusion to date is that no other known agent can heat bone selectively in so effective a fashion.[1,4]

Ultrasonic waves are those in the acoustic spectrum that are beyond the range of the human ear. The Standards Committee on Electroacoustics has set the lower limit of ultrasonic frequency at about 15 kilocycles per second.[5] The frequencies used most commonly in treatment are 800 and 1,000 kilocycles per second. The respective wave lengths in muscle at these two frequencies are 1.92 and 1.54 mm.

Histologic studies have revealed the production of osteogenesis in the bones of normal dogs after exposure to certain amounts of ultrasonic energy.[2] Subsequently, it was considered advisable to test the reproducibility of this phenomenon. We also wished to study the animals for a longer period than the twenty-one weeks used in previous studies and to add roentgenologic evaluation of any changes. This paper is a preliminary report of the study just suggested.

Equipment and Methods

The equipment necessary for production of ultrasonic energy includes a radio-frequency oscillator that generates alternating current of the desired frequency. This current is transmitted through a long coaxial cable to the sound head, or transducer. The long cable permits freedom of motion of the sound head, which is essential for clinical use. Housed in the sound head is a quartz crystal that has been cut so that its natural vibratory frequency coincides with the frequency produced by the particular generator associated with it. This crystal has piezoelectric properties that cause it to change dimensions when an alternating electric current is applied to it. These changes, occurring with high-frequency alternating current, result in vibrations of the crystal of the same high frequency. This is the source of the ultrasonic waves.

Ultrasonic power can be regulated through the generator, and can be measured by means of a power meter calibrated to read in watts representing the total output of the radiating surface.

In most of our work we used the Siemens Sonostat generator, which had a frequency of 800 kilocycles per second; the attached sound head had a radiating surface of 10 sq. cm. We also used the Ultrasonor generator, a product of the Ultrasonic Medical Equipment Corporation. This generator produced a frequency of 1,000 kilocycles per second and had a sound head with a radiating surface of 5 sq. cm.

During exposure to ultrasonic energy, the animals were anesthetized by intravenous injection of 25 mg. of pentobarbital sodium per kilogram of body weight.

Both femora of a series of sixteen dogs were exposed through the lateral aspect of the thigh; a stationary technique was used. Either 15 watts of power with a frequency of 1,000 kilocycles per second or 20 watts with a frequency of 800 kilocycles per second was applied for three periods of five minutes each, with a five-minute interval for cooling between exposures. In four of these animals, a needle thermocouple was inserted into the thigh so that its tip (the site of one thermojunction) was directly over the middle of the femoral shaft. The position of the sound head

Abridgement of thesis submitted by Dr. Ardan to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Master of Science in Orthopedic Surgery.

The Mayo Foundation is a part of the Graduate School of the University of Minnesota.

Dr. Ardan is a Fellow in Orthopedic Surgery at the Mayo Foundation; Dr. Janes is in the Section of Orthopedic Surgery, and Dr. Herrick is from the Biophysics section of the Mayo Clinic.

that gave the most rapid heating of the thermocouple was determined, and the sound head was clamped in this position. The maximal increase of local temperature reached in these four dogs during single exposures ranged from 11.35° to more than 33.55° C. During several exposures the calibrated scale of the meter was exceeded.

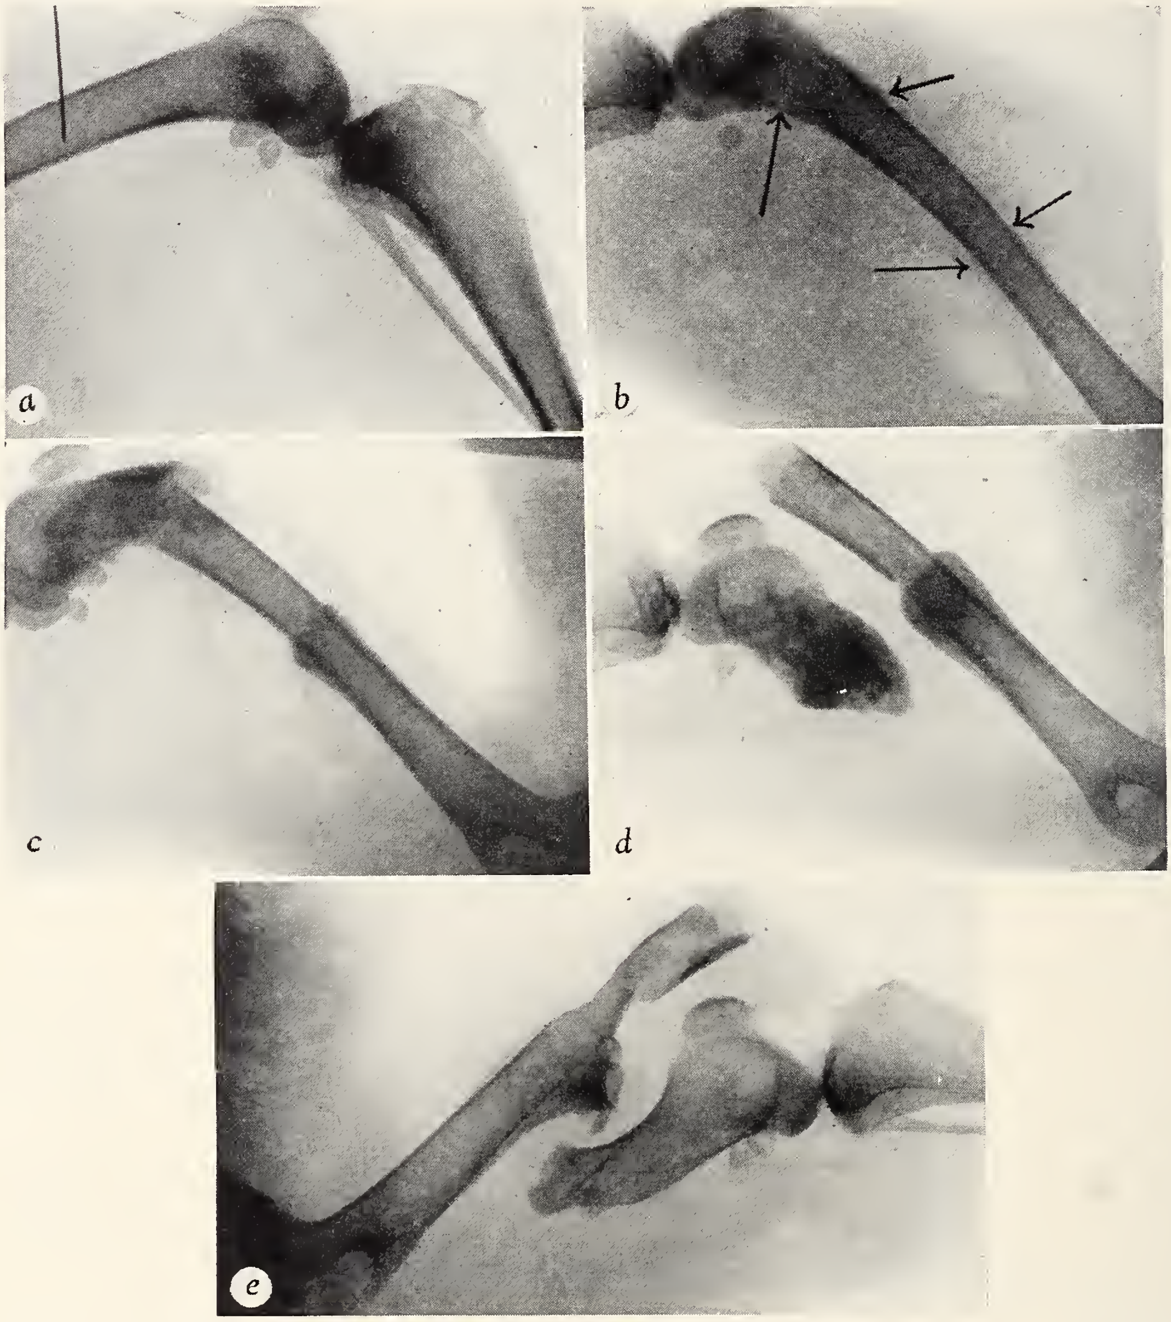

Fig. 1. *(a.)* Femur of dog prior to exposure to ultrasound. Needle thermocouple in position. *(b.)* Same femur ten days after three exposures to 20 watts of ultrasonic power for five minutes. Early periosteal reaction is seen at each end of a segment of bone thought to be necrotic. The field of sound struck the center of this segment. Areas of liquefied fat are seen. *(c.)* Same femur two weeks after application of ultrasound. Note progression of periosteal reactions, the appearance of rarefied bands at each end of the necrotic segment and the fracture through the distal rarefied band. *(d.)* Same femur one month after exposure. Note complete displacement of fractured fragments and no evidence of healing. *(e.)* Same femur five months after exposure. Note resorption of periosteal reactions and necrotic segment. Little effort at healing is present.

The remaining twelve dogs were exposed blindly by attempts to aim the field of sound at the middle of the femoral shaft at a given distance above the lateral femoral condyle.

A coupling medium of mineral oil was used to eliminate any air, which prevents the transmission of ultrasonic energy.

Results

We have evaluated results of a twelve-month roentgenologic and a three-month histologic follow-up in these animals.

Clinically, all animals exposed showed a limp in one or both hind legs for twelve to twenty-four hours after exposure. Other than this, only three dogs showed any early adverse reactions; these were all from the group of four in which the sound had been guided by the thermocouples. In these dogs, small, slowly healing, third-degree burns appeared in the skin of the medial aspect of the thigh directly opposite the sound head, that is, at the point of exit of the ultrasonic energy. In addition, massive edema and apparent paralysis of both hind legs developed in one of these dogs on the fifth day after exposure. This edema and paralysis subsided during a period of fourteen days.

However, other changes were noted in the interim. Figure 1 shows these changes through the stages of periosteal reaction, sequestration, complete dissociation of the fractured fragments with nonunion and, finally, progressive resorption of the initial periosteal reaction and of the necrotic segment of bone. The rarefactions in soft tissue seen in these roentgenograms were interpreted to represent liquefied fat resulting from the intense heat produced during exposure to ultrasound. These changes disappeared in about three weeks. It should be noted that no other dog exposed in this or in any other series in which we have had roentgenologic controls has shown these changes in the soft tissue.

The roentgenologic follow-up demonstrated that of the thirty-two femora exposed, eleven appeared to be completely normal, and thirteen showed minimal evidence of mottled densities with occasional erosions of the cortex. The remaining eight femora showed changes similar to but, for the most part, less extensive than those just illustrated.

All of the twenty-two femora obtained from study of the first eleven dogs showed some gross changes at the site of ultrasonic incidence. Those animals in which x-ray evidence of periosteal reaction had been present showed such reaction grossly (Fig. 2*a*), along with zones of eburnation and zones of pink or brownish discoloration. These discolorations and the eburnation also were apparent in all eleven of those femora which had appeared normal roentgenologically (Fig. 2*b*). We have not made extensive microscopic studies of these latter changes as yet, but the importance of this finding lies in the evaluation of reports of ultrasonic treatment in which the claim that no changes in bone were produced is based on the normal appearance of roentgenograms.

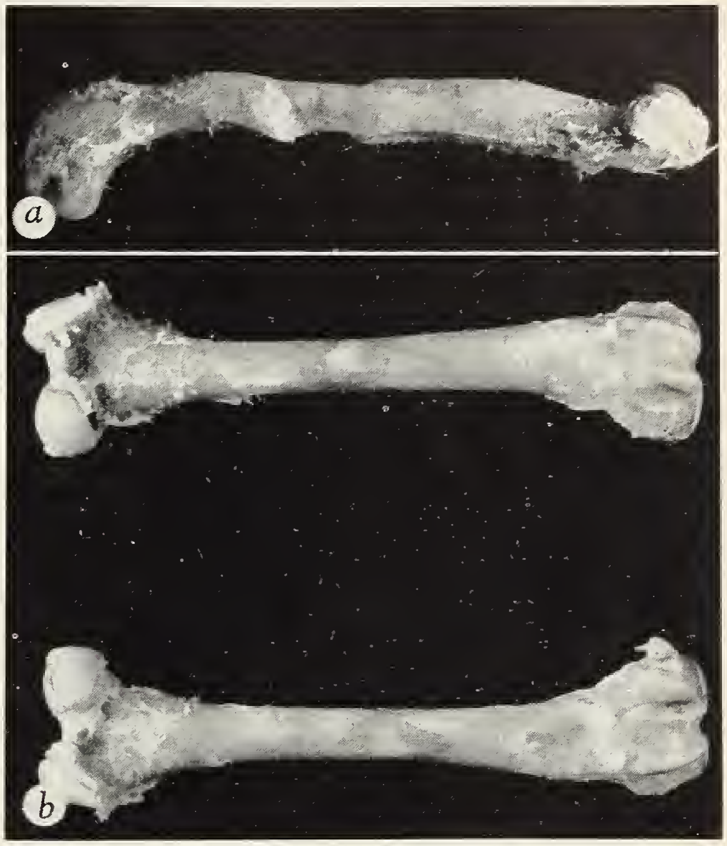

Fig. 2 *(a)*. Femur removed from a dog three months after three exposures to 20 watts of ultrasonic power for five minutes. Note periosteal reactions, with segment of bone between. *(b)* Anterior aspects of femora removed from a dog six months after three exposures to 20 watts of ultrasonic power for five minutes. Note brown discoloration in the region of ultrasonic incidence and the targetlike zone of eburnated bone near the center of these discolorations.

We have surveyed microscopic sections from three femora which exhibited changes similar to those seen in Figure 1. An entire cross section through one of the zones of periosteal reaction is shown in Figure 3*a* for purposes of orientation. The light area at the right end of this section represents a mass of cartilaginous cells undergoing endochondral formation of bone. The slightly darker mass near the left end of the section represents the original medullary cavity that has become filled with dense fibrous tissue. Around this mass can be made out the remains of the original cortex, which has become necrotic and

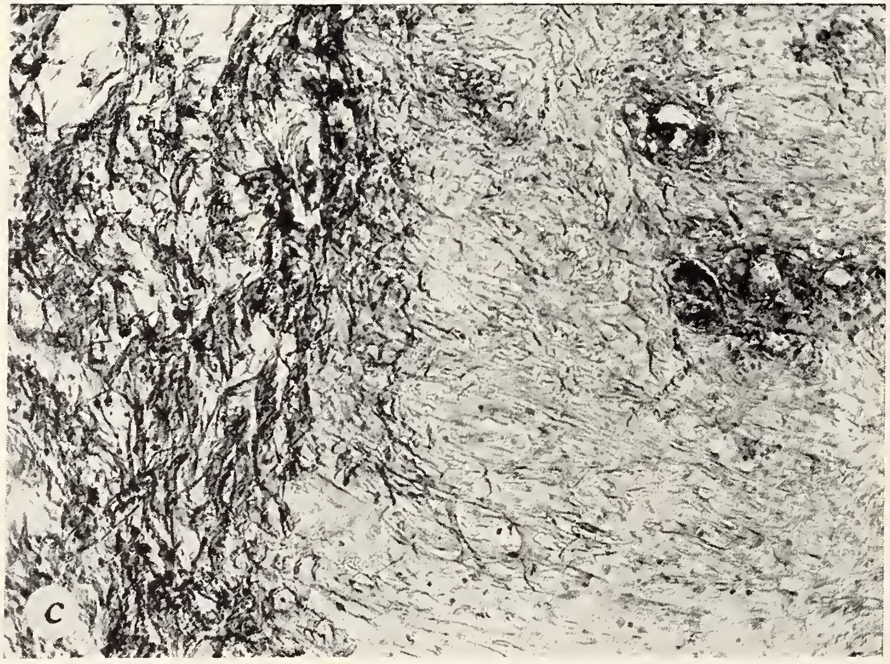
(b.) Endochondral formation of bone occurring subperiosteally.



(c.) Dense fibrous tissue that has replaced the original marrow contents.

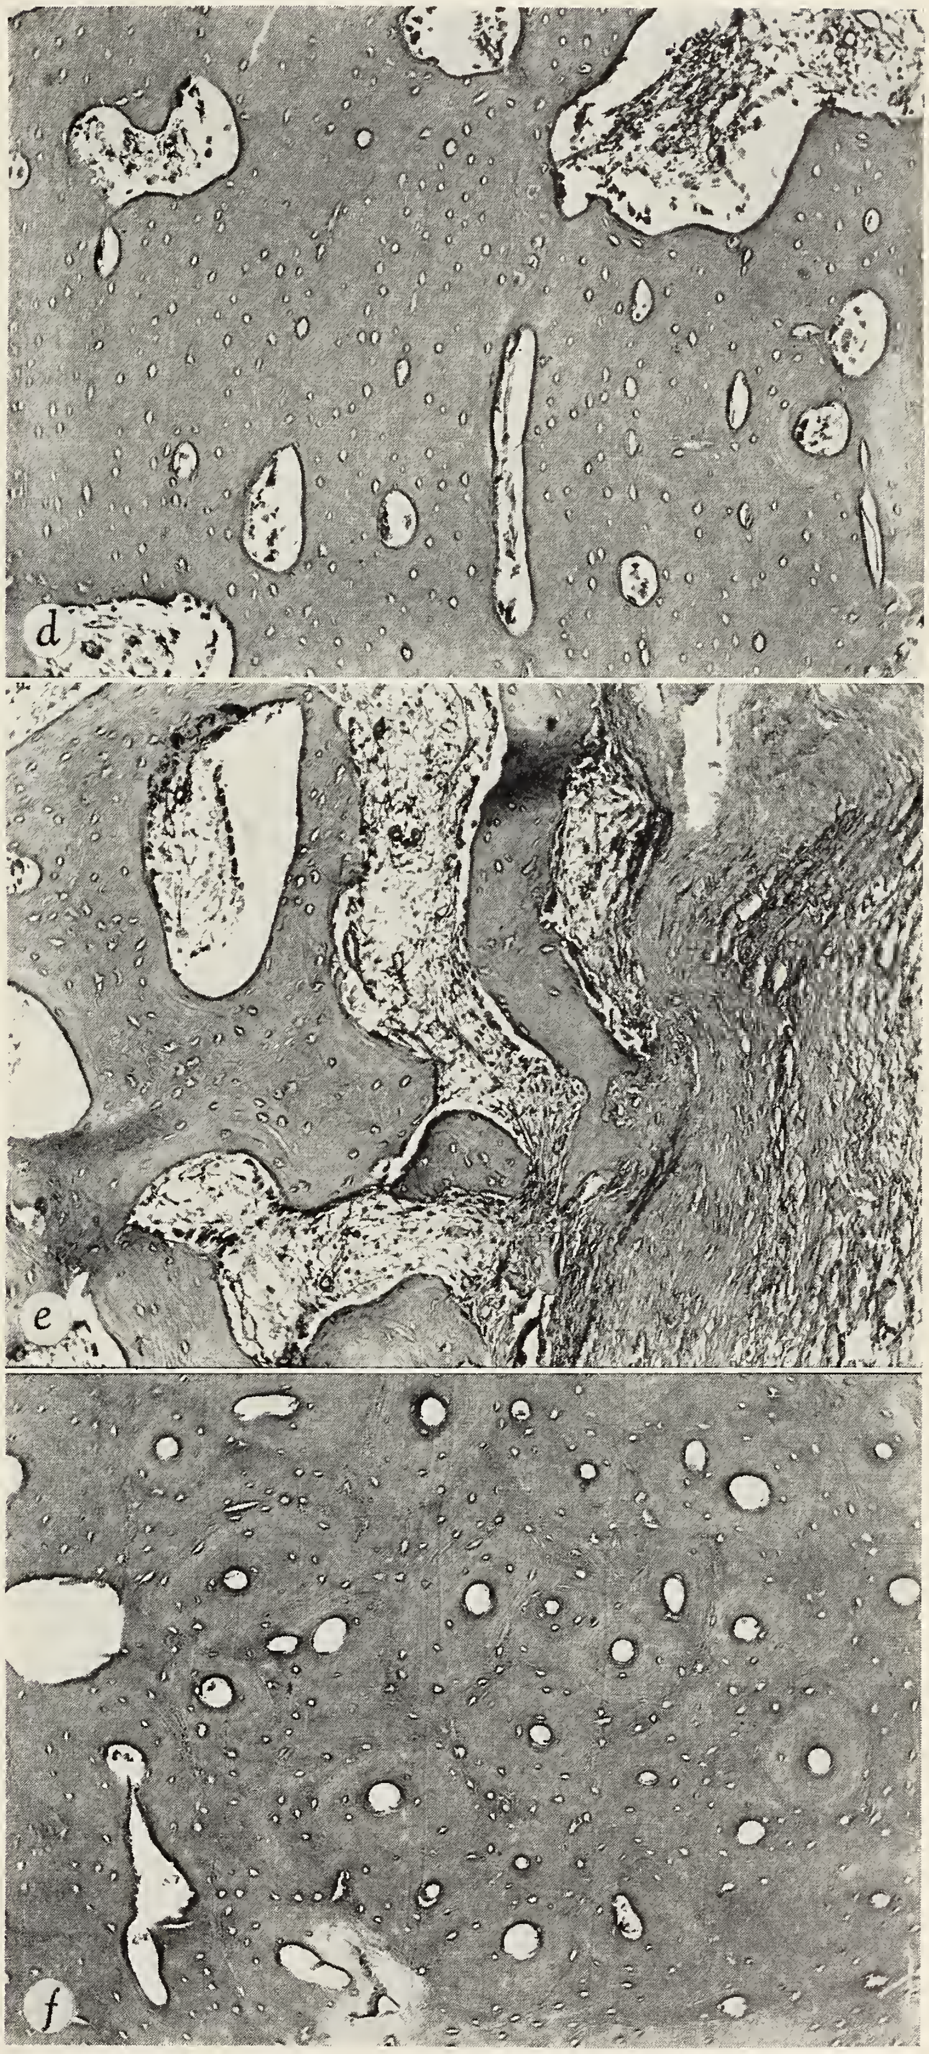


Fig. 3.

(d.) Remains of the original cortex showing loss of normal architecture of cortical bone and loss of osteocytic nuclei.

(e.) Thickened periosteum with subperiosteal formation of new bone.

(f.) Cortex of the necrotic segment between two areas of periosteal reaction. Note loss of osteocytic nuclei but retention of haversian architecture (all hematoxylin and eosin; x95).

broken up. The remainder of the section is comprised of a growth of new bone occurring under an elevated and thickened periosteum. Figure 3*b, c, d* and *e* show higher magnifications of the areas just described. Figure 3*f* is a section through the necrotic segment of the same bone seen roentgenologically to lie between the two zones of periosteal reaction. The loss of osteocytic nuclei can be seen, although the haversian units have remained fairly intact.

Conclusions

1. The response to apparently uniform amounts of ultrasonic energy is variable. All eight femora showing extensive changes occurred in dogs receiving twenty watts of ultrasonic power. However, of the eleven femora that appeared normal roentgenologically, five received 15 watts and six received the larger dose of 20 watts.

2. As in many diseases, negative results of roentgenographic study after exposure to ultrasonic energy do not rule out changes in bone.

3. Ultrasonic energy is capable of dramatic destructive changes in bone, as well as of osteogenesis. It should be noted that the technique of application of ultrasonic energy used in this study is not that advised for clinical use. Although the wattage used was within the limits considered safe for human therapy, the stationary technique concentrated this energy at one spot. With the stroking or massaging technique used clinically, the heating effect is not allowed to become cumulative.

4. Although our results should not be used to condemn the clinical use of ultrasonic energy, they should warn against promiscuous application of this form of energy by untrained personnel.

PRESCRIPTION WRITING

Careless prescription writing may give the patient the impression that there is careless examination and diagnosis. Whether the prescription be written in English or Latin, the important thing is to so write it that it will not be all Greek or Sanskrit to the pharmacist, and that he will know exactly what the prescriber wants.

There were many stories about the illegible handwriting of Horace Greeley, and we just heard a revised up-to-date version of one of these, but it had to do with a physician's prescription.. It concerns a man who got a prescription which was described as having been written in the doctor's usual illegible scrawl. It seems the man recovered before he got around to having the prescription compounded, so he put it in his card case and forgot about it. Later he found a slip of paper in the card case and could not figure out what it was. So he tried it in different ways. For two years he used it as a railroad pass; several times he gained admission to Rockefeller Center Music Hall; it got him into the Yankee Stadium and an exclusive club; he used it as a note from his boss to the cashier for a raise in salary; and finally he brought it home and gave it to his daughter. She played it on the piano and won a scholarship in a conservatory of music.—From the *Pennsylvania Medical Journal,* February, 1952.

DEGENERATION OF THE KIDNEY TUBULES (LOWER NEPHRON NEPHROSIS) ASSOCIATED WITH ELECTROLYTE IMBALANCE

Preliminary Report

CARL O. RICE, M.D., J. H. STRICKLER, M.D., GEORGE FERNANDEZ, M.D., and NATHANIEL LUFKIN, M.D.
Minneapolis, Minnesota

NOT INFREQUENTLY the pathologist has been unable to account for the cause of death in a patient who has died without adequate organic pathology.

In many of these instances degeneration of the kidney tubules may have been found in varying degrees of severity. This has not usually been considered to be adequate to account for the death of the patient unless it has been associated with anuria.

The finding of degenerative changes in the kidney tubules has been called lower nephron nephrosis,[14] transfusion reaction,[1,6,7,9] renal anoxia,[17] crush syndrome,[2,4,9] traumatic anuria,[3,9,18] septic abortion kidney,[21] pigment nephrosis and a variety of other things.[5,11] In addition it has been found to be associated with burns,[12] severe trauma, toxemia of pregnancy, mushroom poisoning, delirium tremens, black water fever,[9,16] carbon tetrachloride, ethyl glycol poisoning,[10,20] sulphanilamide sensitivity,[8,13] and retroperitoneal hemorrhage associated with obstetrical difficulties.[19,22]

We have reviewed many of the case reports in the medical literature portraying degeneration of the kidney tubules. All of those cases which indicated electrolyte studies revealed an electrolyte imbalance. This finding, however, was given no further consideration.[15] In all of the other cases, where electrolyte studies were not done, the nature of the illness or the symptoms make it appear logical to expect that an electrolyte imbalance could have existed in those cases. The symptoms which suggest this possibility are vomiting, diarrhea, fistula, extensive edema, exudative losses (burns), dehydration,[14] abdominal distension, ileus, septicemia, inadequate nutrition and the common practice of administering glucose and saline. All of these factors are notorious in their ability to cause a loss, or a shift, of the electrolytes.

Complete blood electrolyte studies and water and electrolyte balance studies were done on 102 major surgical cases for other purposes.

TABLE I.

	No Organic Postmortem Findings Group I	Organic Postmortem Findings Group II

Esophageal v.v.		1
Mesenteric thrombosis		1
Small bowel obstruction		1
Total	8	12

Among these were eight patients who died without adequate organic postmortem findings to account for the death and twelve patients who presented adequate pathology. Both of these groups had suffered an electrolyte imbalance and showed tubular degeneration in the kidneys. The nature of their primary disease is shown in Table I.

In Group I, the disease condition was corrected surgically, but in all instances the patients did poorly in the postoperative period and finally died without evidence of organic complications. All of these eight patients presented tubular degeneration in the kidneys as the only significant postmortem finding.

In Group II, three of these patients were not operated upon as the stage of their disease did not seem to warrant it. The others had emergency surgery. All of these patients did poorly and died with sufficient organic pathology to account for their death. In addition tubular degeneration in the kidneys was found at postmortem examination. In Group II, the diseases were, on the whole, more severe than in Group I in that many of these patients suffered initially from peritonitis in addition to the underlying primary disease. All of these patients in Group I and Group II were known to have an electrolyte imbalance. Anuria or oliguria was a finding in four of these cases. It was not a consistent

finding. Nine of these patients received blood transfusions. Only one mild transfusion reaction was encountered. The nature of their blood electrolyte imbalances is recorded in Table II.

There was no constancy in the abnormal electrolyte pattern. Every patient was found to be abnormal in three or more items. On the whole when the electrolyte pattern was more extensively disturbed, the degree of tubular degeneration was likewise greater.

A characteristic study pattern can be observed in Table III in which it can be seen that the patient suffered a severe electrolyte imbalance in all items. She died twenty-five days after surgical release of common duct stone. During this postoperative period she continued to vomit and was given only glucose and saline until three days before her death when the electrolyte imbalance was recognized and an attempt made to correct it. Postmortem examination revealed no organic cause for death. The kidney tubules showed extensive (4+) tubular degeneration (Fig. 1).

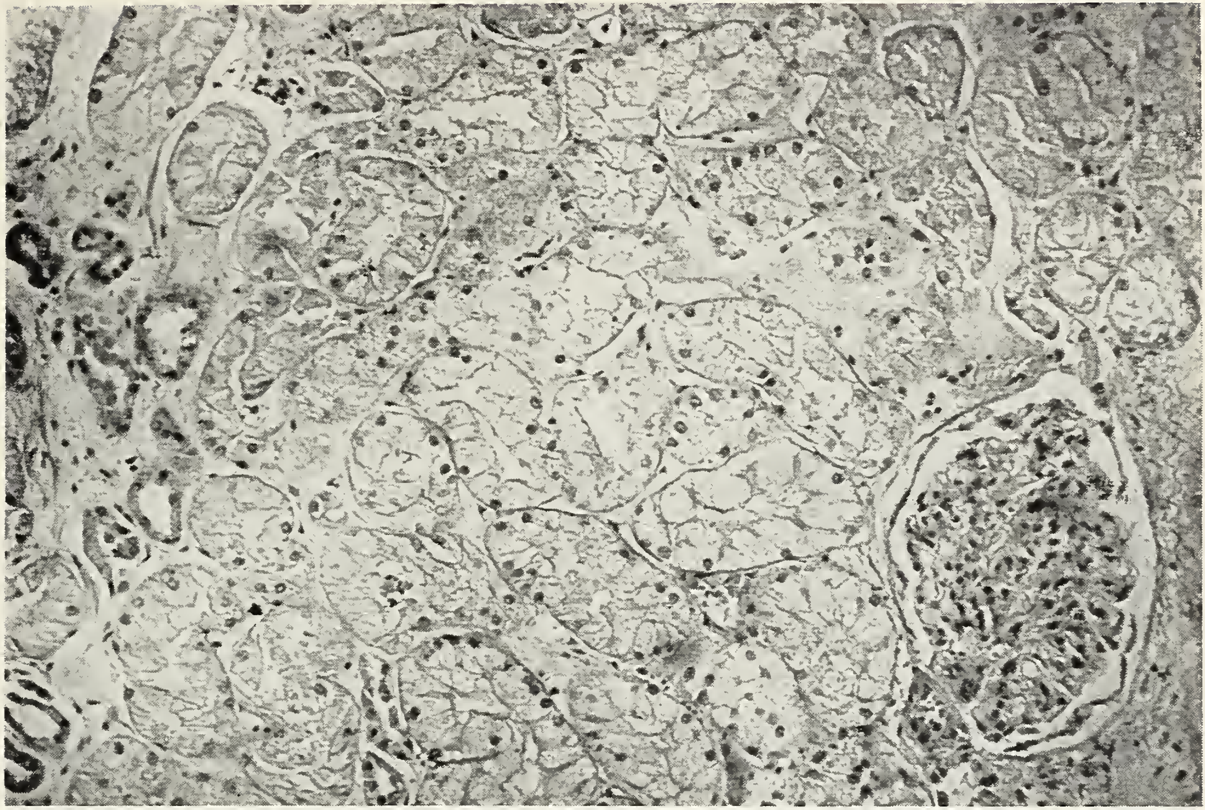
Another instance in which the patient recovered from the electrolyte imbalance with death attributable to peritonitis is shown in Table IV. This patient died from peritonitis eight days after she had recovered from a severe electrolyte imbalance. In this instance evidence of regenerating tubular disease was shown in the kidneys (Fig. 2). This finding was also observed in two other patients who had recovered from their electrolyte imbalance and died eleven days and twenty-four days, respectively, later from other factors.

A third group of patients were studied for control. Among these were serious diseases such as carcinomatosis, diabetic coma, etc., so that if the disease could have caused tubular degenera-



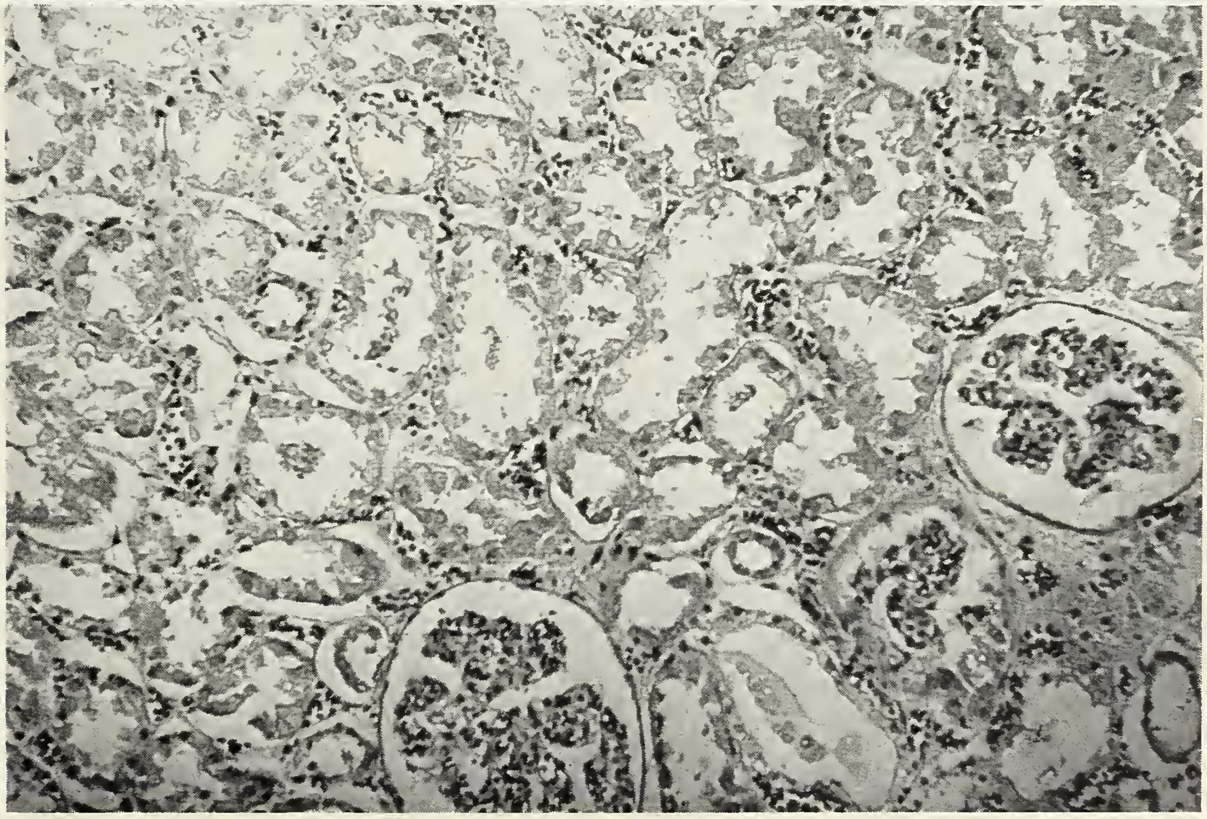


Fig. 1. Obstructive jaundice; operative release. Twenty-five days of glucose and saline. Electrolyte imbalance severe (See Table III). Tubular degeneration 4+ involving all areas of the kidneys. Cells hydropic-glomeruli normal. No oliguria. No organic cause for death found post mortem.

Fig. 2. Ruptured ileitis, peritonitis. Postoperative hypopotassemia, hypochloremia, alkalosis and then acidosis and uremia from which patient recovered eight days before death. Postmortem examination revealed peritonitis and septicemia. Tubular degeneration in scattered areas (2+) showing evidence of regeneration.

tion it should have been present in some of these. Complete studies were not done on all of the control group, but the history and physical findings suggest that an electrolyte imbalance should not have been present. Likewise, an examination of the kidneys obtained postmortem in a series of sudden deaths failed to reveal tubular degeneration in any of them.

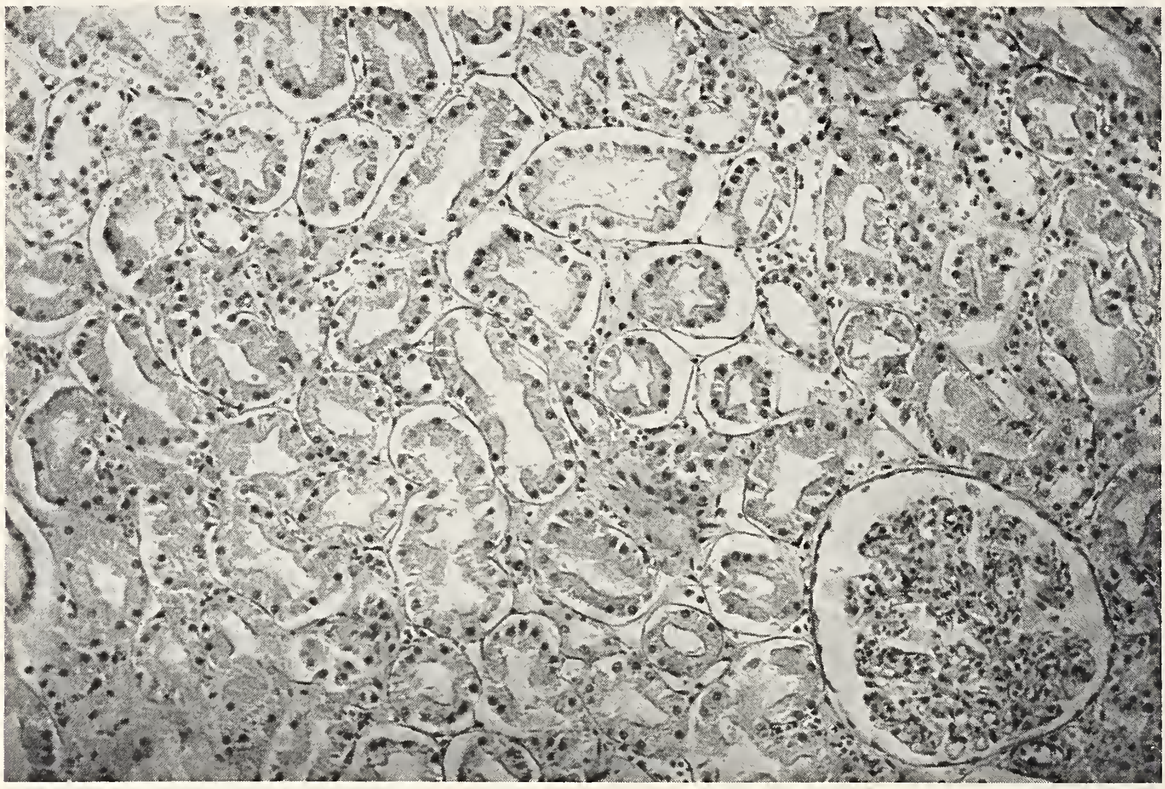

Fig. 3. Normal kidney.

One of the cases in this control group suffered severe disease, but was known definitely not to have an electrolyte imbalance. This case is illustrated in Table V (Fig. 3).

Comments and Conclusions

The blood urea nitrogen was found to be elevated in thirteen of the patients. It was found to be higher in those who presented the greatest degree of tubular degeneration. This is probably merely an index of the inadequacy of the kidney function.

The blood sugar was found to be elevated in all instances, but seemed to have no correlation with the degree of tubular degeneration or the severity of the electrolyte imbalance. The elevated blood sugar was not considered to be due to diabetes, except in two known diabetics, but was thought to represent a manifestation of the metabolic disturbance which is present in some cases of surgical trauma. Tubular degeneration of the kidneys was not found to be present in two diabetic coma cases in the control group and, therefore, it seems that the elevated blood sugar need not be considered a factor in causing the tubular degeneration.

Water balance studies indicate a positive water balance in four cases, negative water balance in one case, water equilibrium in eight cases and insufficient data in seven cases. There appeared to be no correlation between the water balance and the degree of tubular degeneration or the electrolyte imbalance.

The consistency of the known electrolyte imbalance in Group I and Group II associated with the postmortem finding of tubular degeneration, and the absence of an electrolyte imbalance in the control group associated with the finding of normal kidney tubules, suggests that the pathogenesis of tubular degeneration of the kidneys may be related to an electrolyte imbalance.

It is our conclusion from these findings that when tubular degeneration is found in the kidneys at postmortem, a retrospective evaluation of the clinical picture would, in all probability, indicate that an electrolyte imbalance had existed. When microscopic evidence of tubular *regeneration* is evident, it can also be presumed, on the same basis, that the patient was in the process of recovering from an electrolyte imbalance.

Any studies which are done in the future endeavoring to establish the pathogenesis of tubular degeneration of the kidneys must take into consideration the electrolyte and water balance status of the subject before concluding that tubular degeneration of the kidneys is of more specific origin.

FINDINGS OF FIRST YEAR'S STUDY OF DOCTORS IN SERVICE

Results of the first year's survey of physicians leaving active military service are carried in a report recently issued by the AMA's Council on National Emergency Medical Service. Information obtained from this continuing questionnaire study is being used as the basis for a series of conferences with Department of Defense and Armed Forces representatives in an effort to improve the utilization of medical personnel and the formulation of a more effective voluntary officer procurement system.

During the first year of the study—July 15, 1952, to August 1, 1953—a total of 3,948 completed questionnaires revealed that the average time spent in service was 24.7 months; average tour of duty in U. S., 7.6 months; average tour of foreign duty, 17.1 months. Twenty-nine per cent felt there was overstaffing, 20 per cent understaffing and 51 per cent adequate. Of those assigned to domestic duty, 53.4 per cent were engaged in treating military personnel, 28.3 per cent in treating military dependents and 18.3 per cent in "other"; while of those assigned to overseas duty, 51.8 per cent treated military personnel, 23.8 per cent dependents of military personnel and 24.4 per cent "other." Answers to the question regarding the *type of medical care* provided for *other than* military personnel indicate that in the Army and Navy the most frequent type was outpatient care, while in the Air Force it was obstetrics and gynecology.

Regarding the question, how national and local medical associations can better serve their members in service, the following activities were suggested—more information via a newsletter, etc.; personal visits by civilian doctors to evaluate grievances; invite military doctors to civilian medical meetings; assist in locating position after discharge; assist in preventing evasion of military service; distribution of questionnaires to physicians in service; provide specialists for clinical conferences.—*AMA News Notes.*

PREVENTION OF MAJOR COMPLICATIONS DURING ANESTHESIA

JOHN W. PENDER, M.D.
Rochester, Minnesota

PREVENTION of complications is largely a matter of philosophy on the part of the anesthetist. That an ounce of prevention is worth a pound of cure is a growing philosophy in modern anesthesia. Prophylactic anesthesia requires that the anesthetist understand not only the problems of anesthesia but also the problems of surgery, as well as the individual physiology and pathology of each patient. Armed with such knowledge and the experience gained from the conduction of many previous anesthesias, the anesthetist can anticipate complications and can institute measures to prevent their occurrence. The anesthetist's ability to anticipate complications in their incipiency is most important in the matter of insuring safety to the patient and uninterrupted successful completion of the operation. Such ability is more important than any ability to revive the patient heroically after the jaws of death have begun to close.

Three requisites for prevention of complications are awareness of changes in the patient, early diagnosis of changes, and early treatment of minor complications. These will be discussed separately, first as to the means available today for practicing them, and later as to the means we may hope to have available after ten to fifteen years of progress.

Awareness

Awareness of changes in the patient is the most important requirement and also the most difficult to practice constantly and adequately. Man is aware of his environment through his five senses: sight, smell, taste, hearing and touch. John Snow used these same senses to study his patients, and during the one hundred years between his time and ours, improvements in the efficiency of these senses have been slow. At present, prevention of complications must depend mainly on the constant and uninterrupted use of these unaided senses. Certainly such prevention will always require alertness as well as competence on the part of the anesthetist. To be constantly in contact with the condition of the patient from moment to moment, the anesthetist must necessarily be in close proximity to him at all times. An arm's length is possibly the maximal distance that should separate the two and the practice of some early anesthetists of leaving the operating room without providing for intelligent constant attendance of the patient is not generally tolerated today. The anesthetist must necessarily be in close proximity in order to employ his five senses in unceasingly evaluating the condition of his patient.

Hypoxia is the greatest threat to the safety of most patients and is one of the most serious of complications. The symptoms of acute severe hypoxia are easily recognized and attract the attention of the surgical team as well as the anesthetist. On the other hand, the symptoms of chronic hypoxia of a slight but dangerous degree may be insidious; hence, they can easily be overlooked by the busy anesthetist who may be responsible for duties other than the constant observation of the patient. Too frequently the history, after cardiac arrest, is: "The patient was just fine and everything was going along nicely when all of a sudden the heart stopped." At necropsy no cause of death can be found and a diagnosis of "vagovagal" reflex may be made. This diagnosis made by exclusion may or may not be correct. Operations on the human heart itself have given some of us an opportunity to observe the stamina of this organ and to develop a high regard for its ability to function under difficulty. It seems logical that in some cases of unexplained cardiac arrest the history of the sequence of events leading up to the arrest may not have been just as they seemed even to the honest anesthetist. Before arrest, some hearts have likely been subjected to unfavorable circumstances but have been able to maintain some function under stress. The arrest, instead of being an initial sudden occurrence, was the climax to a slow decrease in the ability of the heart to compensate for the stress. If the anesthetist had become aware that the heart was under stress, preventive measures could have been taken to

---

From the Section of Anesthesiology and Intravenous Therapy, Mayo Clinic, Rochester, Minnesota.

remove the unfavorable circumstances and the ultimate arrest could have been avoided.

All the numerous ways in which hypoxia can occur cannot be mentioned here but they should always be in the back of the mind of the alert anesthetist. Regardless of the type of surgery and the manner of draping, some part of the patient's skin or nails should be exposed in good light, so that the color can be observed and cyanosis prevented. As will be mentioned later, the color of the skin is a grossly inaccurate indication of the degree of oxygenation of the blood. However, it is certainly better to be able to observe the color of the skin at frequent intervals than not to be able to see any part of the patient. I like to have my hand on the patient's face, neck, chest or abdomen where I can feel the respiratory motion, even when I can clearly see the motion of the breathing bag on the anesthesia machine. In this way I am doubly aware of the respiration through two senses—sight and touch. If the respiratory passages become partly obstructed, I may be warned by a third sense—hearing.

If a finger is kept in the vicinity of an artery of the patient, a subconscious contact can be maintained with the circulatory system and its efficiency. Even though the anesthetist is not able to concentrate constantly on the rate and rhythm of the pulse, any sudden change in these characteristics will have an effect similar to the sudden stopping of a ticking clock in a quiet room. The recording of the blood pressure and pulse rate at frequent intervals is indispensable but at best it is an intermittent method, and to prevent complications a constant method is desirable. Even the extremely conscientious anesthetist cannot record all these readings much more frequently than once every five minutes, and when other duties must be attended to, the interval becomes much longer.

Being a co-operative and industrious individual, the anesthetist frequently becomes responsible for too many operating room chores such as assisting with draping, adjusting surgical lights, adjusting the operating table, wiping the surgeon's brow and so forth. Even the administration or supervision of the supportive therapy may be his responsibility. These added duties must of necessity distract his attention from the condition of the patient, much to the patient's disadvantage. Even the maintenance of his own anesthesia equipment in a properly functioning condition is sometimes a dangerous distraction from attention to the patient.

It is, therefore, evident that to become instantly aware that a complication is impending the anesthetist must be constantly aware of what is happening to and in his patient. There is much room for improvement by the development of more attentive habits by anesthetists, but on the other hand, it is humanly impossible for any individual to effect complete concentration on any factor for hours on end without interruption. As will be discussed later, the answer to this problem is the development of instruments which can function unceasingly. It seems possible that awareness might be made mechanical.

Diagnosis

Let us imagine for a moment that we have reached that stage of development of the specialty of anesthesia where constant awareness has been made possible and the anesthetist is immediately conscious of every change as it occurs in his patient. Then he must diagnose the change and evaluate it. This diagnosis will likely never be mechanical, and it is the function which makes anesthesia necessarily the practice of medicine in contrast to a series of technical maneuvers. The ability to diagnose is based on an understanding of the basic sciences. In addition, judgment is required, and judgment is based primarily on training and experience.

Suppose the blood pressure of the patient decreases. The anesthetist must examine many factors which might have exerted an influence to bring about the change. Then from the facts at hand he must make a decision. Basically, he must decide whether the fall in pressure is the result of a decrease in cardiac output or a decrease in peripheral resistance. Then he must go further and further into detail by constantly asking himself the question, "Why?" Rarely he may be able to make a definitive diagnosis and know minutely what is happening in his patient. All too frequently, however, the ability to make more than a provisional diagnosis is hampered by a lack of facts about the individual patient. The anesthetist may know volumes of physiology which is based mainly on animal experiments or he may know from anesthesia textbooks the symptoms and signs of many classes of complications, but rarely is he able to determine accurately the physical or chemical changes in each patient as they occur. Most of the time he only has a gross idea about even the concentration of the gases which the patient is breathing from the bag on the anesthesia machine.

Diagnosis is necessary primarily for the purpose of indicating treatment and is not usually thought of as a preventive measure. The early and accurate diagnosis of minor complications and their effective treatment is the only way of preventing major complications. The old saying, "Great oaks from little acorns grow," seems to apply here—apparently few major complications develop suddenly from a normal state. Instead, most are preceded by a series of progressively severe minor complications which either were not recognized or were misdiagnosed or mistreated. When a cardiac arrhythmia develops during anesthesia, the anesthetist must first realize that the arrhythmia exists, then he must diagnose it, evaluate its significance, and, if necessary, institute treatment to eliminate it and prevent more serious cardiac complications. But under ordinary circumstances, how will he be able to make a definitive diagnosis? He may think the arrhythmia is due to premature contractions, but how can he know whether the origin of the premature contractions are auricular, nodal or ventricular? When an experienced cardiologist would hesitate to venture diagnosis from palpation alone, how can an anesthetist definitely differentiate a tachycardia of supraventricular origin from a tachycardia of ventricular origin? Yet, the accurate diagnosis is important because the former would likely not demand immediate treatment, but the latter should be treated immediately, perhaps with an intravenous dose of a procaine-like drug or quinidine. How can one know the heart rate of a patient with both an auricular fibrillation and a variable pulse deficit? The answer to all these questions is evident—by the use of an electrocardiograph—yet how many patients have an electrograph attached before a routine operation?

Early diagnosis is the crux of the whole problem of cardiac arrest on the operating table. Preparation of emergency equipment and an outline of procedure for action by the surgical team is important but is of no use in salvaging a valuable citizen unless the anesthetist recognizes cardiac arrest at almost the moment it occurs. The average delay of three to five minutes before cerebral damage occurs is usually needed to open the chest and start cardiac massage. If the anesthetist is not aware of the complication or is not able to make a definite diagnosis until after two or three minutes have elapsed, the chance of saving an undamaged patient will be slim. Those who have been faced with the problem know that such a diagnosis is difficult, when dire consequences may result from a snap and unverified diagnosis.

What evidence is necessary for the early diagnosis of cardiac arrest: lack of ability to get a blood-pressure reading or to feel a radial pulse? Several times every month each of us is jolted by the sudden inability to get a blood-pressure reading or feel a pulse, only to find that some mechanical defect has occurred in our apparatus or that the arm has been put in such a position that the circulation has been impeded. The investigation of such factors in the differential diagnosis of cardiac arrest takes time. The raising of an alarm the very instant that we suspect cardiac arrest only to admit a mistake within a few moments several times a month will cause the surgical team to lose faith in us. Then when a real cardiac arrest occurs, we will lose time convincing them that it is not just another false alarm. If the thorax or abdomen is open, the surgeon may be asked to verify our suspicions by palpating the heart or great vessels, but if the operation is elsewhere in the body, it is more difficult to make the diagnosis definitely enough and quickly enough to justify thoracotomy. Future progress in overcoming the bad results of cardiac arrest is not likely to come from the development of better methods of treatment but from the development of better methods for making an early and certain diagnosis of the complication.

Treatment

Early accurate diagnosis by an alert and competent anesthetist makes early treatment possible. It is early and adequate treatment that prevents the bad results of major complications. Adequate treatment frequently depends on the preparation of equipment, drugs and plans in anticipation of the complication before it happens. It is almost correct to say that the good anesthetist must of necessity be a pessimist, always expecting the worst even when he is doing his utmost to prevent it. From previous experiences the anesthetist knows which complications are more likely to occur in a particular patient with a particular disease, undergoing a particular operation, by a particular surgeon, under a particular type of anesthesia, and in a particular position. So in being forewarned, the thinking anesthetist should keep himself forearmed and prepared to treat such expected complications adequately.

It is sometimes necessary to treat unusual complications at unexpected times. The fact that no preparation has been made for the prevention or treatment of such complications partly explains why they seem to be fatal more often or to be followed by serious consequences. From the reports in the literature, cardiac arrest would seem to occur more frequently in good-risk patients than in poor-risk patients. If so, this fact might be explainable on the basis that poor-risk patients are observed closely every moment, that every diagnostic aid is used to follow the condition of such patients, and that preparation is made to treat the major complications which are expected but which are prevented in their incipiency. On the other hand, in the ordinary good-risk patient no complications are expected, so that no greater than ordinary preparation is made to prevent or treat unexpected complications. Much attention to monotonous detail is necessary to keep everything set up and in good working order. In addition to being a pessimist, the careful anesthetist must also possess some of the characteristics of the overly meticulous spinster housekeeper as far as his equipment is concerned. Even the presence or absence of an efficient aspirating catheter may make the difference between life and death for the anesthetized patient whose respiratory passages have become obstructed with liquid or semisolid material. As a general statement, it might be said that the prevention of major complications during anesthesia depends on the willingness of the anesthetist to spend his time and effort fussing with little details which at the moment seem inconsequential.

In summary, it may be said that major complications are best prevented by treating them before they happen.

Instrumentation for the Future

It has been shown that continuous monitoring of the patient is necessary in order for major complications to be prevented. The anesthetist with his unaided senses is able to provide only intermittent monitoring. The shorter the intervals between observations the safer it is for the patient, but it is humanly impossible for the anesthetist to provide continuous observation of the patient without instruments to aid his senses. A few of the instruments, mostly electronic, which have shown promise of being of help will be mentioned.

Cardiotachometer.—From leads similar to those used for electrocardiography the pulse rate may be shown on a dial or recorded on paper or film. Whereas the anesthetist with his finger on a pulse can only estimate the average pulse rate, the cardiotachometer can indicate the rate from one beat to another and is therefore more sensitive and more accurate. An alarm device can be used with the cardiotachometer, so that if the pulse rate falls below a predetermined figure a bell will ring, a light will flash or some other alarm will go off to warn the anesthetist that all is not well with his patient.

Direct Blood-pressure Recorder.—The determination of blood pressure by the auscultatory, oscillatory or palpation method is inaccurate and subject to variation in individual interpretation. The direct recording of the blood pressure through a needle or small flexible tube in a peripheral artery is objective, more accurate and constant. In addition, there is promise that from the recorded pulse contour a reasonably accurate estimation of the stroke volume of the heart can be calculated,[3] and, therefore, the cardiac output can be followed from minute to minute.

Electrocardiograph.—The value of this instrument is recognized by all. At present it offers the most practical means of diagnosing cardiac arrhythmias and allowing the anesthetist to be cognizant of changes in the heart before these changes reach the status of major complications. Like so many of the electronic instruments, it introduces an explosion hazard into the operating room. However, instruments are available whereby the electrocardiographic pattern can be shown on a cathode-ray screen which is enclosed in an explosion-proof housing, safely situated at the side of the anesthetist. By pressing a switch the anesthetist can cause any significant patterns to be recorded on the direct-writing electrocardiograph which has been set up in a nonhazardous area.

Electro-encephalograph. — The determination of the depth of anesthesia by the signs and symptoms as outlined by Guedel is not accurate. The signs vary from individual to individual, and the interpretation of a group of signs is not always the same to different anesthetists. There is good evidence to indicate that the electrical activity in the brain decreases as the depth of anesthesia increases. The integration of the electrical activity of the brain as recorded with an electro-encephalograph is therefore a valid means of objectively measuring depth of anesthesia, which can be shown on the dial of an anesthesia depth meter or recorded. This principle has been used to activate a servomechanism whereby the anesthetic agent is automatically administered if the electrical activity of the brain increases and the depth of anesthesia decreases below a preset degree, whereas the rate of administration of the anesthetic agent is automatically decreased if the anesthesia becomes too deep and the electrical activity of the brain decreases.[1]

Thermometer.—During recent years much attention has been focused on the changes in body temperature which occur during anesthesia and on the effects of these temperature changes. Hyperthermia during anesthesia and operation is generally considered to be detrimental to the welfare of the patient. Especially in children the body temperature may rise to dangerous levels under conditions which are apparently similar to those well tolerated by most adults and some children. A marked rapid rise in body temperature demands immediate treatment, but how is the anesthetist to know that it is rising unless it is being recorded? Electronic and mechanical thermometers are available for continuously recording temperature in various parts of the body during anesthesia. Induced hypothermia is being employed more and more, especially during operations on the heart and great vessels for cyanotic heart disease. This hypothermia must be controlled, and to be controlled some convenient type of thermometer must be used.

Oximeter.—No condition is so likely to result in major complications as a severe decrease in the efficiency of the system for transporting oxygen to the tissues. It is well known that as the oxygen content of blood decreases, the color tends to change from red to blue, but the gradation of the change is too small to be accurately estimated by the human eye. Some of the newer models of oximeters make it possible for the delicate changes in the color of arterial blood to be constantly monitored by a photoelectric cell and for the changes to be shown on a dial or recorded on paper or film as absolute percentages of saturation of the arterial blood with oxygen. The Pauling type of oxygen meter makes possible rapid and accurate determination of the concentration of oxygen in anesthetic mixtures of gases and has been of great aid in studying the effects of known mixtures.

Carbon-dioxide Meter.—Carbon dioxide is of almost as much importance as oxygen, and the concentration in the blood is kept within narrower limits even than the concentration of oxygen. Accurate control is provided by nature for a very important reason and it behooves us as anesthetists to strive to see that nature is not hindered in providing safeguards. Anesthesia may mask the symptoms of change in carbon-dioxide concentration which occur readily in the unanesthetized individual. For that reason instruments for determining the concentration of this gas are important. Extremely accurate intermittent determinations are possible by use of the mass spectrometer, but continuous determination of the concentration in the respiratory gases is possible by several other methods.[2]

pH Meter.—One reason why carbon dioxide is so important is that it plays a big role in keeping the hydrogen-ion concentration within the narrow range compatible with life in the mammal. The increasing use of the combination of respiratory depressing agents and artificial respiration during anesthesia has increased the demand for instruments to show the changes in pH of the blood during the time when the respiratory center or other parts of the respiratory mechanism are paralyzed. Many unexplained major complications during anesthesia may well be the indirect effect of an unsuspected radical alteration in the pH of the blood. So far as I know, no instrument is available at present for continuously recording this factor, but in the future such instruments will be developed.

Up until now, only the advantages of instrumentation have been stated. The disadvantages are readily evident. Most instruments are still in the experimental stage of development and have been used largely for research studies, while commercially available models which are sturdy and simple enough to be used routinely by the clinical anesthetist have not been perfected. In their present form, many instruments are bulky, and if all that have been mentioned were employed at once they would fill the average-sized operating room. Most are electronic and because of the explosion hazard cannot be used when inflammable anesthetic agents are being administered. The operation of most of these instruments is complicated and the services of personnel trained in electronics are required. Even if the anesthetist has the ability to set up, run and service the instruments, he will not be able to administer the anesthesia and care for the instruments at the same time.

All these objections are legitimate but need not be appalling. Much work is yet to be done in perfecting the instruments for clinical use, but at least we have an ideal, a hope and a goal to work toward. Just because most of us cannot build an automobile or cannot service any defect in operation of our automobile does not keep us from deriving benefit from the use of automobiles. It would be a sad state of affairs if everyone who rode in an airplane had to be able to fly it unaided.

The aircraft industry makes a good comparison to the specialty of anesthesia. Before and during World War I, the pilot had a crude machine and few mechanical aids. He flew "by the seat of his pants" in about the same way that most of us give anesthesia today. However, the complexity of new developments did not deter the members of the aircraft industry, so that today huge ships with panel after panel of dials and safety devices travel faster than sound, sometimes without a human pilot. The anesthetist also must eagerly accept mechanical aids as they become available in order to facilitate the safety of his patients and put anesthesia on a really scientific basis. The problem of personnel will have to be solved in the same manner as used by the surgeons, namely, by the development of a team. An anesthesia team will be more expensive than the individual anesthetist, but the American public has always been willing to finance anything which it can be convinced is for its own good. When the surgeon himself could not attend to all details of an operation, the surgical team was accepted without question. It is up to us as anesthetists to provide safety and then to sell it to our patients. Safety means freedom from complications.

Summary

1. The factors in the prevention of major complications during anesthesia are awareness of change in the patient, early diagnosis and early treatment of minor complications.

2. Continuous monitoring of the patient is possible only by the use of instruments which are now being perfected.

102 Second Avenue S.W.

The contrast in tuberculosis mortality rates of the Japanese in Hawaii as compared with the rates in Japan is of interest. In Hawaii, the rate for the five-year period, 1918 through 1922, was 132 per 100,000 as compared with 12 in 1952. In Japan, on the contrary, the rate for 1918 through 1922 was 233 and, in 1951, the last available figure was 111. Similar differences exist in other races such as the Filipinos, Chinese, and Koreans, all having much lower rates in Hawaii than those reported in their respective countries of origin. In all probability, higher living standards and better nutrition are the most important factors to account for these differences.—HASTINGS H. WALKER, M.D., *American Review of Tuberculosis,* December, 1953.

PAROTID TUMORS

A Report of Six Cases

RAYMOND F. HEDIN, M.D.
Red Wing, Minnesota

FEW TUMORS have received such exhaustive studies and are still so poorly understood as tumors of the parotid gland. The surgeon approaches parotid tumors with timidity because of facial nerve paralysis resulting from their removal. The pathologist is hesitant about prognosticating which tumors are apt to recur after removal. As a result many patients are advised to forego surgery for a period of "observation" because of the fear of resulting facial nerve paralysis; occasionally x-ray therapy is offered as a therapeutic measure. These factors contribute to the rather discouraging results which are associated with treatment of parotid tumors.

Parotid gland tumors are rather rare. At Los Angeles County Hospital in 37,000 consecutive autopsies,[17] the incidence of parotid tumors was found to be only .023 per cent. Except in large tumor clinics, few surgeons have had much experience with these tumors. In 1943 a survey was made in the Philadelphia area[14] where it was found that in twenty-four hospitals, during a quarter of a century, there were 233 patients with mixed tumors of the parotid gland operated on by seventy-three surgeons. The average was 3.2 patients each. Only six surgeons had ten cases or more.

The origin of parotid tumors is not well understood.[3,6] Virchow in 1863 was the first to describe these tumors.[12] Since many of them contained cartilage, he believed them to be of mesoblastic origin and termed them "diffuse endochondromas." Cohnheim in 1877 speculated that in early embryonic development, more cells were produced than necessary in the salivary glands, and tumors often occurred because of their great capacity for growth. Wartmann in 1879 believed these tumors to be endothelial in origin. Krompocher in 1908, observing the basal layers of stratified epithelium, called these tumors basalomas. Favata[5] in 1948 was able to culture, in vitro, cells from mixed tumors and keep them alive for 140 days. He believed that there is evidence that mixed tumors may be derived from cells lining the ducts of salivary glands. Ligation of the salivary ducts in dogs is said to produce mixed tumors of the parotid gland. The interference with the flow of secretion in the production of these tumors may explain why recurrence happens so frequently when only a portion of the gland is removed in man. Of great importance is the recent work of Gross[7] who has produced salivary gland carcinomas in mice by injecting a filterable agent. In eighty-four mice of a certain strain, he was able to produce bilateral salivary tumors in fifteen mice. They developed on an average of 3.3 months after injection.

The conflicting ideas relative to the origin of parotid gland tumors have made a clear classification difficult.[20] A simple classification[15] which has been suggested is as follows:

1. *Cysts*—These are caused by obstruction, atresia, or congenital defects in the duct system. They are rare and benign.
2. *Adenomas*—Adenomas are well encapsulated tumors and grow slowly. They are composed chiefly of glandular tissue and are benign.
3. *Adenocarcinoma*—This group of neoplasms are usually stated to comprise about 10 per cent of all parotid tumors, although some reports suggest that 40 per cent would be a more accurate figure. They are poorly demarcated tumors that rapidly infiltrate surrounding structures. They include the onocytoma and cylindroma and are extremely malignant.[18] The recurrence rate is thought to approach 100 per cent, and usually takes place within a five-year period, 85 per cent recurring within three years, although some of these malignant tumors have been known to recur as long as forty years after removal. They invade vital structure and may metastasize to lymph nodes, bone, liver, spleen, lung, pancreas, thyroid, ovaries, adrenals, dura and brain. Total removal of the parotid gland is imperative, and many believe a radical dissection of the node-bearing area is indicated. Deep x-ray therapy has proven to be of little value in these tumors, as most parotid tumors are radioresistant.
4. *Mixed Tumors*—This group is the most controversial and comprises about 75 per cent of all parotid tumors. They are composed of three component structures: (a) complexes of epithelial cells in cords or duct-like structures; (b) connective tissue of the mucoid type; (c) substances identified as cartilage or pseudo-cartilage. They usually have a definite capsule and are rarely infiltrative. The histological structures are extremely variable[19] and are, therefore, difficult to classify. Mixed tumors are notorious for recurring after they have been removed. The recurrence rate is stated to be between 25 per cent and 40 per cent; the average recurrence time is seven years. Because they are prone to recur, there is persistent disagreement

---

Inaugural thesis presented before the Minnesota Academy of Medicine, Saint Paul, Minnesota, November 11 ,1953.

among pathologists as to whether mixed tumors of the parotid gland are benign or malignant. It does not seem possible to foretell the behavior of a mixed tumor from microscopic sections alone. The clinical course must be correlated and even then an accurate prognosis is often impossible. McFarland,[14] who has made an extensive study of mixed tumors of the parotid, attempted to find out with what accuracy pathologists could predict from microscopic sections the probability of recurrence. He submitted to eight eminent pathologists sections from fifty mixed tumors that had been followed for many years. There was no unanimity of agreement on any of the tumors. Fifty-two per cent of the tumors were diagnosed correctly and 48 per cent inaccurately diagnosed as to recurrence. The highest percentage of accuracy for any of the eight eminent pathologists was 63 per cent. From this study alone it can be seen why surgeons and pathologists are bewildered when confronted with mixed tumors of the parotid gland. Using Ewing's[4] criteria of malignancy, these tumors have the following characteristics:

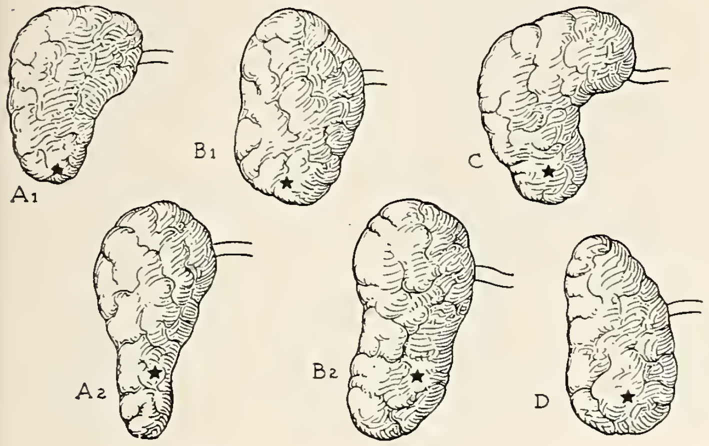

Fig. 1. Various shapes of the parotid gland (after McCormack, L. J.; Cauldwell, R. W., and Anson, B. J. Courtesy Surg., Gynec. & Obst.).

(a) *Infiltrative growth.*—Because these tumors have a definite capsule they rarely infiltrate. Should the capsule be broken, either from surgery or trauma, the tumor may infiltrate into orbit or brain.

(b) *Recurrence after removal.*—As stated previously, recurrence is far too frequent[10] and this may take place as long as twenty or thirty years after removal. For this reason, the word "cure" should be used with extreme caution.

(c) *Metastasis.*—Metastases are rare. McFarland found this to occur in but 2 per cent of his cases.

(d) *Local interference with function.*—Mixed tumors may cause deafness if the external auditory canal is obstructed. Movements of the jaw may be restricted and pressure on the facial nerve may cause facial paralysis on the affected side. If Stensen's duct is obstructed, cystic retention of secretion may result.

(e) *General toxic action of absorbed tumor products.*—There is no absorption of tumor products unless the tumor ulcerates and bacterial invasion results in sapremia or septicemia.

(f) *Local tissue destruction.*—Mixed tumors are covered by the skin of the cheek, which allows for extensive stretching and for this reason ulceration seldom occurs. The fifth and seventh cranial nerves at times become involved, causing pain and paralysis.

With these data at hand it becomes evident that in all cases of mixed tumors of the parotid gland, the prognosis should be guarded and the patient advised as to all possible eventualities.

5. *Entodermal Cysts.*—This group consists of the adenolymphomas or papillary cystadenoma lymphomatosomas. They are rare, benign and arise from lymphoid conglomeration that surrounds the first bronchial cleft and resemble tonsillar tissue. They should be removed.

6. *Tumors of Nonglandular Origin.*—These parotid tumors are extremely rare and may be composed of blood vessels, nerve[23] lymphoid or fibrous tissue. Hemangiomas of the parotid gland, with few exceptions, have been found only in infants.

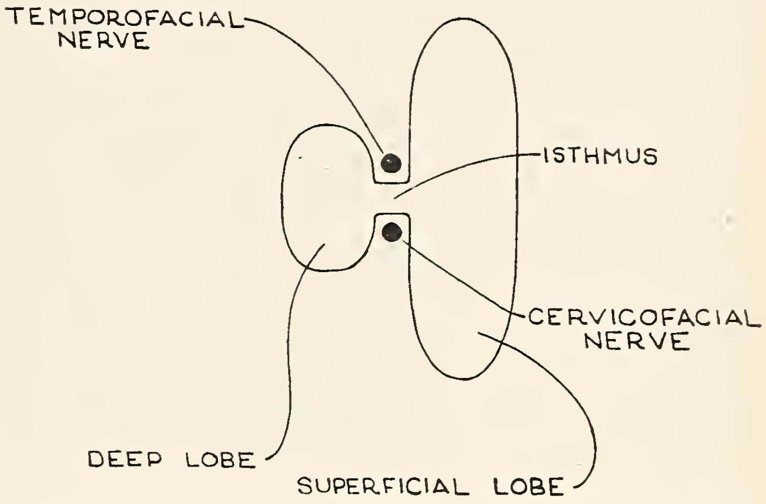

Fig. 2. Arrangement of the lobes of the parotid gland showing the isthmus at which site the facial nerve divided into the larger temperofacial branch and the smaller cervicofacial branch.

Anatomy: The parotid gland develops during the eighth week of fetal life. The glandular structure varies in shape (Fig. 1) and is held together with loose areolar tissue. There is no definite capsule, but the gland is covered by fascia which is continuous with the fascia of the neck as it passes upward from the sternomastoid to the zygomatic arch. It is bounded in front by the ramus of the mandible and posteriorly by the external auditory meatus, tympanic plate and the base of the styloid process. The gland overlies the masseter muscle. Stensen's duct emerges from the anterior aspect of the gland and courses over the masseter muscle piercing the buccinator muscle to enter the oral cavity. In the past most anatomy books have stated that the facial nerve passes *through* the parotid gland substance. This information has led most surgeons to deem it impossible to remove tumors of the parotid gland without injuring the nerve and most were hesitant to try. Fortunately the researches of McWhorter,[16] and later McCormick, Cauldwell and Anson[11] have enlightened us to the true relationship of the parotid gland and the facial nerve. They found the parotid gland is composed of a larger superficial lobe with many variable prolongations and a smaller deep lobe which are joined together by an isthmus. They further found that the facial nerve does not traverse through the gland, but rather *between* the two lobes and that the nerve invariably divides to embrace the isthmus (Fig. 2). These anatomical facts have facilitated and encouraged surgeons to attempt removal of tumors without fear of resulting facial paralysis (Fig. 3). The facial nerve emerges from the stylomastoid foramen and does not give off branches until it encounters the isthmus where it divides into two principal divisions, the temperofacial and the cervicofacial nerves. The former is two or three times the size of the latter and supplies most of the upper part of the face. These divisions usually have five terminal branches: temporal, zygomatic, buccal, mandibular and cervical. These branches anastomose freely. McCormick, Cauldwell and Anson (Fig. 4) from their dissection of one hundred individual facial nerves, concluded that the anastomosis of the terminal branches could be catalogued as belonging to one of eight types. With these facts at hand the surgeon has been reassured as to the possibility of successfully removing these tumors without resulting disfigurement to the patient.

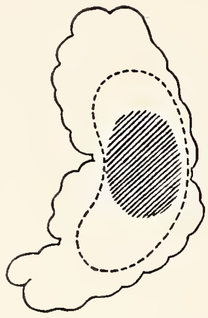

Fig. 3. Relationship of the larger superficial lobe, isthmus (Cross-batching), and smaller deep lobe (broken line) (after McCormack, L. J.; Cauldwell, R. W. and Anson, B. J. Courtesy Surg., Gynec. & Obst.).

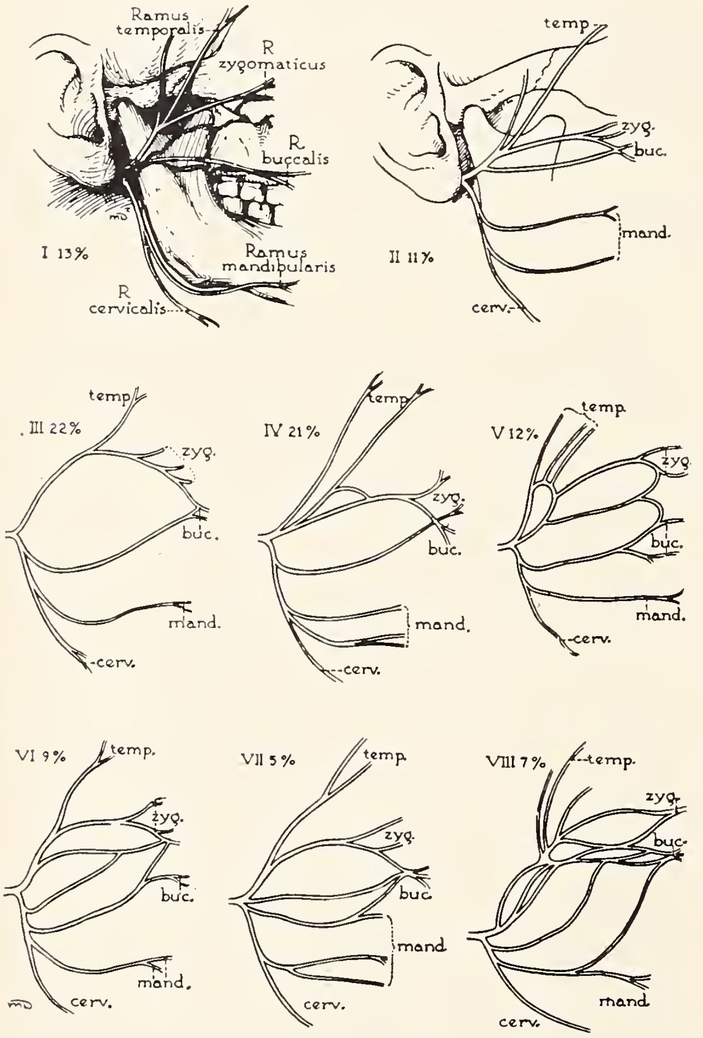

Fig. 4. Variations in the branches of the facial nerve can be catalogued into eight different arrangements.

Most patients seek treatment for parotid tumors because of embarrassment from the unsightly swelling, limitation of motion of the mandible, pain or sudden rapid growth of the tumor.[22]

Treatment: Treatment should be directed toward the complete removal of all tumor tissue with the hope of no recurrence of the tumor.[1,21] Various procedures[17] have been carried out consisting of simple enucleation of the tumor, lobectomy, or radical removal of the entire parotid gland along with the node-bearing areas. When one is dealing with adenocarcinoma, probably the procedure of choice should be the complete removal of the parotid gland.[9] Whether or not excision of the node-bearing area is indicated depends on the size and involvement of the tumor. In the case of the mixed tumors, lobectomy would appear to suffice. X-ray therapy is reported to be ineffective in the treatment of most types of parotid tumors. Technically intratracheal anesthesia, prevention of blood loss by temporary or permanent ligation of the external carotid artery, and meticulous care in separating the two lobes of the parotid gland and preserving the facial nerve will facilitate the successful removal of parotid tumors.

Case Reports

Case 1. W. P., male, aged sixty, (Fig. 5) presented himself complaining of a tumor on his left cheek which he stated had been present for two years. He stated it had been getting larger during the past two or three months. The tumor was the size of a hen's egg and was located below the zygoma and anterior to the angle of the jaw. A diagnosis was made of a parotid

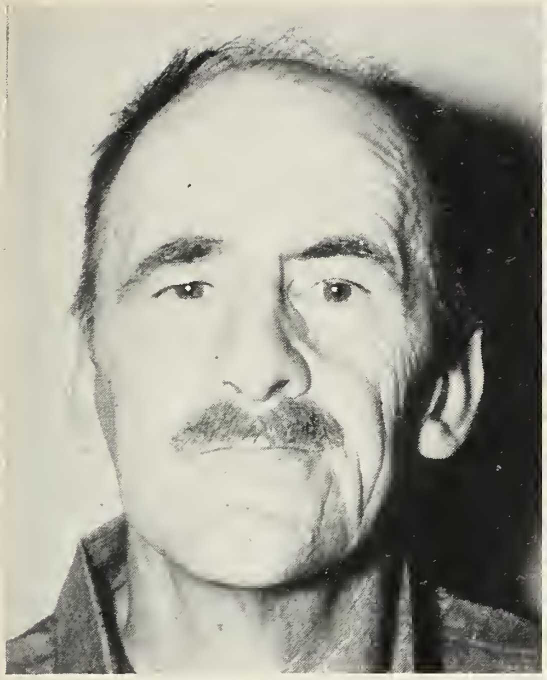

Fig. 5. W. P.—Mixed tumor of the parotid. Tumor removed by simple excision without injury to the facial nerve, except for slight inability to elevate the forehead on the affected side.

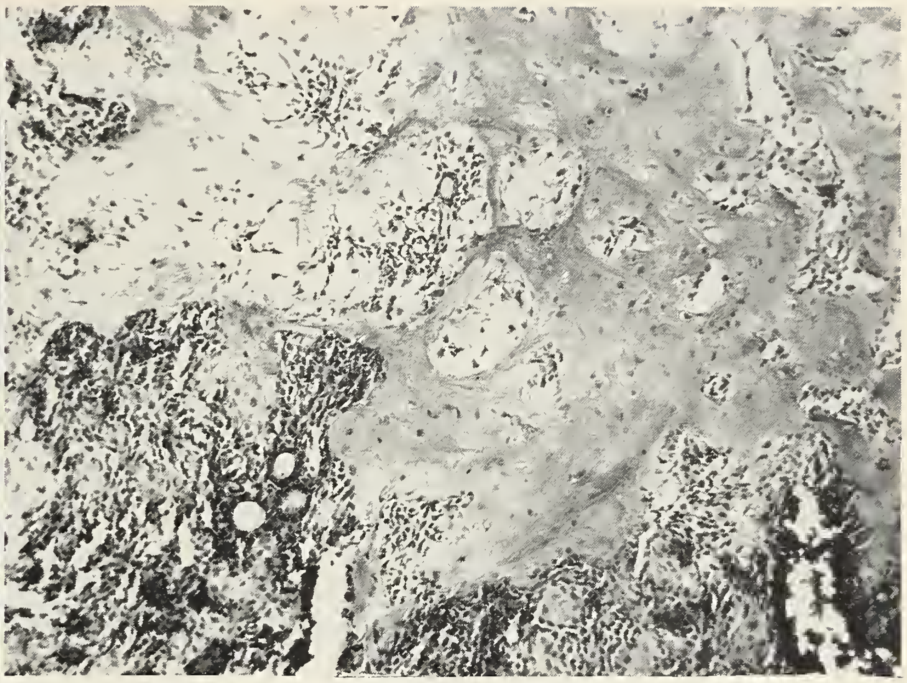

Fig. 6. Microscopically, tumor was composed of cartilage, myxomatous tissue, and masses of epithelial tissue. Some definite glands are also formed. Mixed tumor of the parotid.

tumor. On November 1, 1946, under local anesthesia the tumor was excised and it was thought at the time of surgery that a portion of the facial nerve was "in the tumor" and was sacrificed. He was discharged from the hospital on the fifth postoperative day and made an uneventful recovery. He has no facial paralysis except his inability to elevate his forehead on the affected side. There has been no recurrence.

Pathological diagnosis: Mixed tumor of the parotid gland. The tumor measures 3½ x 2½ cm., is firm, grayish-yellow in color. It is friable and appears to be poorly encapsulated. Microscopically the tumor is composed of cartilage, myxomatous tissue, and masses of epithelial tissue. Some definite glands are also formed (Fig. 6).

This patient should have had a general anesthetic and lobectomy.

Case 2. M. C., female, aged twenty-nine, complained of a swelling just below the angle of her jaw which would vary in size. She stated she had noticed the swelling for the past year. The tumor was compressible and slightly tender. A diagnosis was made of a parotid tumor and on June 28, 1948, she was operated on under local anesthesia. A cyst was encountered which contained a cloudy yellowish fluid. The cyst was excised. She made a rapid recovery and was discharged on the second postoperative day. There was no evidence of facial paralysis and there has been no recurrence (Fig. 7).

Pathological report: Cyst from the parotid gland shows no evidence of neoplasm. There appears to be a fibrous cyst wall present.

Fig. 7. M. C.—Moderately large cyst of the parotid gland excised without evidence of facial paralysis.

Case 3. L. F., female, aged seventeen, presented herself complaining of a painless swelling just below the angle of the jaw on the right side. She stated the tumor has been present for two years. She had been advised six months after onset to have the tumor removed but refused. The tumor increased in size and when first

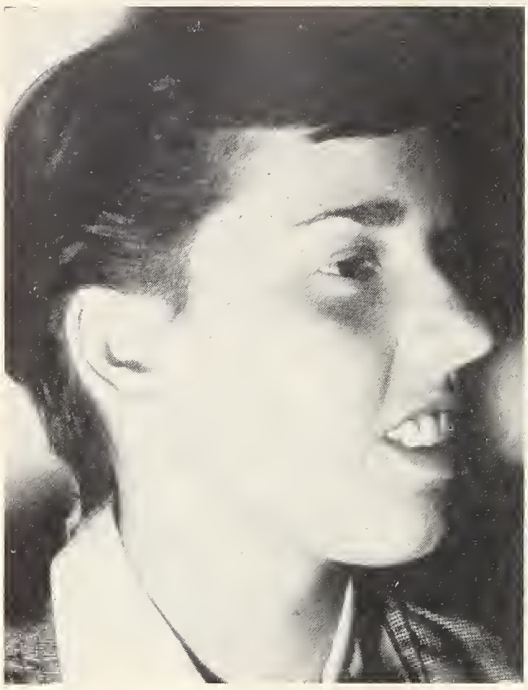

Fig. 8. L. F.—Mixed tumor of the parotid gland removed without evidence of resulting facial paralysis.

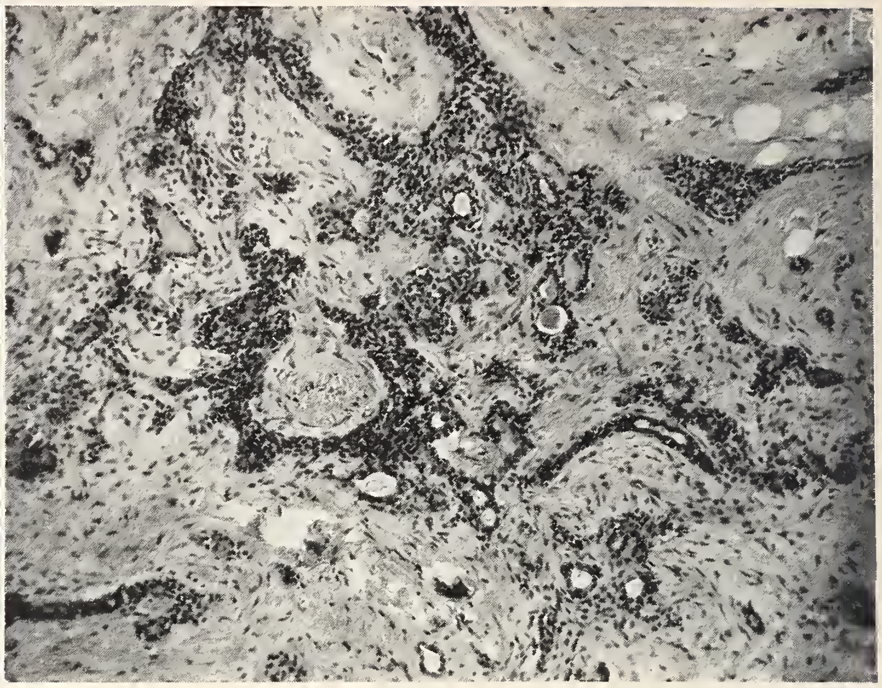

Fig. 9. Microscopically, tumor was composed of dense hyaline connective tissue stroma embedded in which are plaques of fairly well differentiated cartilage together with rather irregular cords and columns of small, deep staining epithelial cells. Mixed tumor.

seen at our clinic the tumor was the size of a lemon. On September 16, 1952, surgery was carried out under general anesthetic. There was a definite encapsulated tumor which extended from the parotid gland and was intimately adherent to the submaxillary gland. The submaxillary gland was removed along with the tumor (Fig. 8).

Pathological report: Specimen measures 4 cm. in diameter. It is firm in consistency and white in color. It has the gross appearance of malignancy. Microscopic examination shows the tumor to be composed of a dense hyaline connective tissue stroma embedded in which are plaques of fairly well differentiated cartilage together with rather irregular cords and columns of small deep staining epithelial cells. A few gland structures are formed. Diagnosis: Mixed tumor of the parotid gland (Fig. 9).

This tumor was confusing inasmuch as it seemed as much associated with the submaxillary gland as the parotid gland. Because of the type of the tumor she is being closely followed for possible recurrence.

Case 4. E. H., female, aged fifty-three, noticed a swelling in front of her right ear in August, 1952. The swelling increased in size and in November, 1952, her family doctor removed an "infected gland." The incision healed slowly and the swelling recurred. She presented herself at our clinic in June, 1953. A check was made of the pathological diagnosis in 1952 and it was found that the "infected gland" had been reported as a cylindroma and its significance not appreciated. On June 2, 1953, using intratracheal anesthesia, the external carotid artery was ligated and complete removal of both lobes of the parotid gland was carried out. Very little difficulty was encountered in preserving the facial nerve. The convalescence has been uneventful except for a transitory facial paralysis that is rapidly disappearing (Fig. 10).

Pathological report: Tumor mass measures 6 x 4 x 3 cm. It is grayish in color and very firm in consistency. There is definite infiltration with no evidence of encapsulation. Microscopic sections of the tumor show it to be composed for the most part of solid sheaths, cords and columns of epithelial cells which are markedly undifferentiated and definitely infiltrating. In a few areas glands are formed. Definite mitotic figures are present. The picture is that of a carcinoma rather than the usual mixed tumor. Diagnosis: Cylindroma of the parotid gland (Fig. 11).

This tumor was removed successfully with preservation of the facial nerve and a close follow-up will be carried out.

Case 5. S. N., aged forty-three, complained of a painless swelling over the left parotid region of two years duration. He first noticed it while shaving and had observed a slight increase in size. A diagnosis was made of a parotid tumor and excision was carried out under local anesthesia on January 11, 1941. A well encapsulated dark bluish tumor 4 x 2 x 2 cm. was removed. At the very end of the dissection the capsule was inadvertently entered and there was a slight spillage of the granular contents of the tumor. The wound was

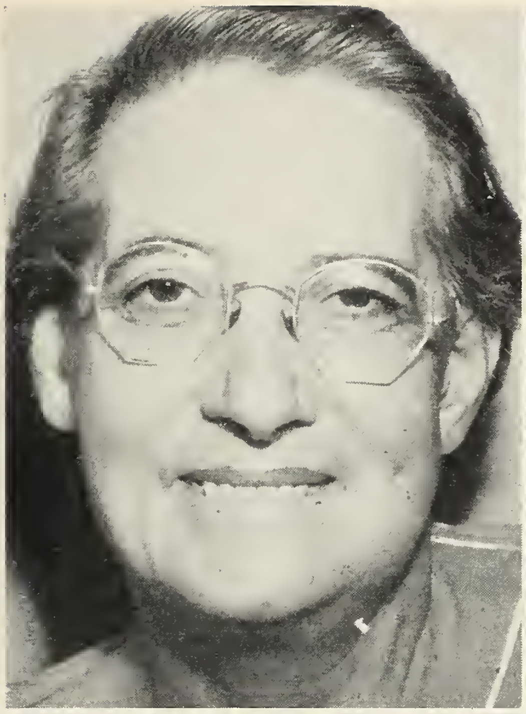

Fig. 10. *(above)* E. H.—Cylindroma of the parotid gland. Excision of both lobes of the parotid gland with preservation of the facial nerve. Four months postoperatively there remains a slight facial paralysis which has been rapidly improving.

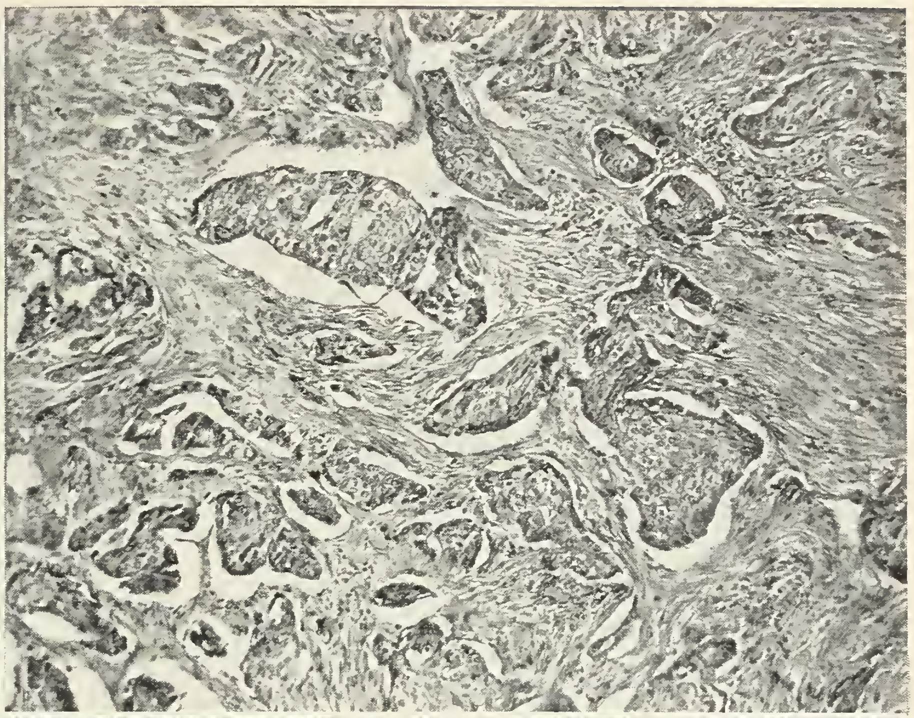

Fig. 11. *(above)* Microscopic appearance of the cylindroma showing solid sheaths, cords and definitely infiltrating. These tumors are malignant tumors.

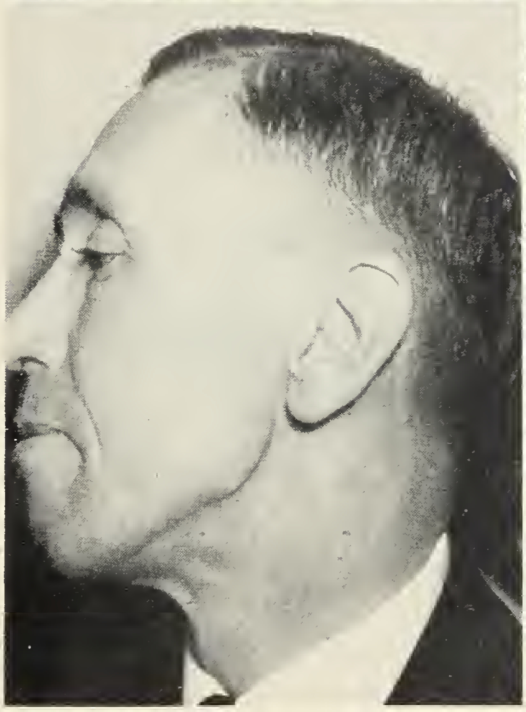

Fig. 12. *(below)* S. N.—Adenocarcinoma, grade three, removed in 1941, by local excision followed by x-ray therapy without evidence to date of recurrence. There has been no evidence of facial paralysis.

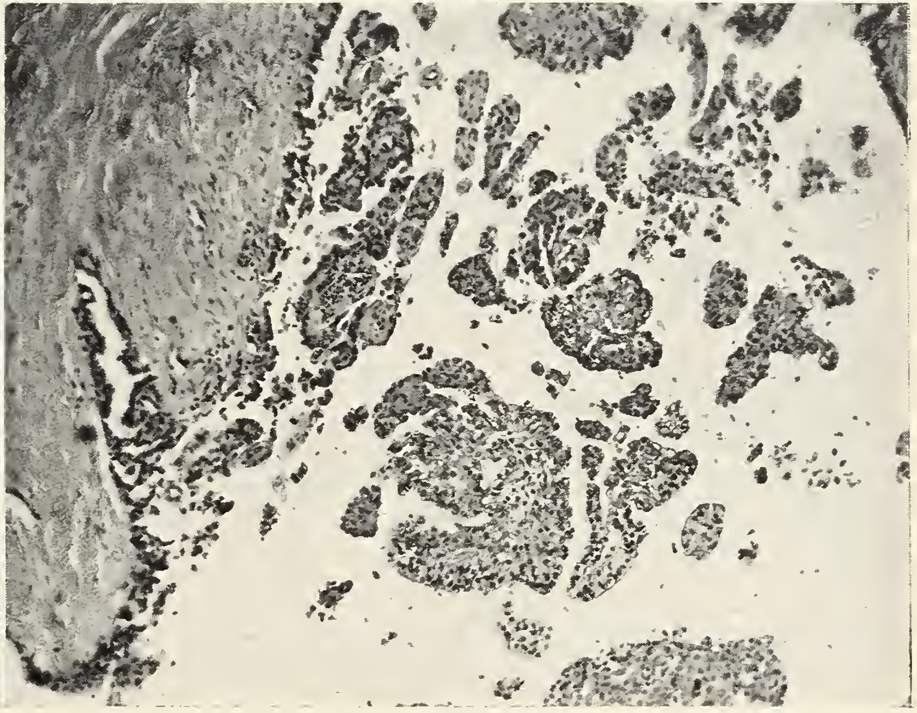

Fig. 13. *(below)* Microscopic appearance of adenocarcinoma of the parotid gland. This malignant tumor was reported by Dr. A. C. Broders, Mayo Clinic, as "adenocarcinoma, grade three, more malignant than the average grade three."

thoroughly irrigated with saline. The patient left the hospital after a few hours and healing was by primary union without any evidence of facial nerve impairment (Fig. 12). The tumor was reported by Dr. A. C. Broders of the Mayo Clinic as being "adenocarcinoma, grade three, more malignant than the average grade three." X-ray therapy was given following the healing of the incision (Fig. 13).

In the light of our present knowledge this patient should have had a complete extirpation of his parotid gland with possibly a dissection of the

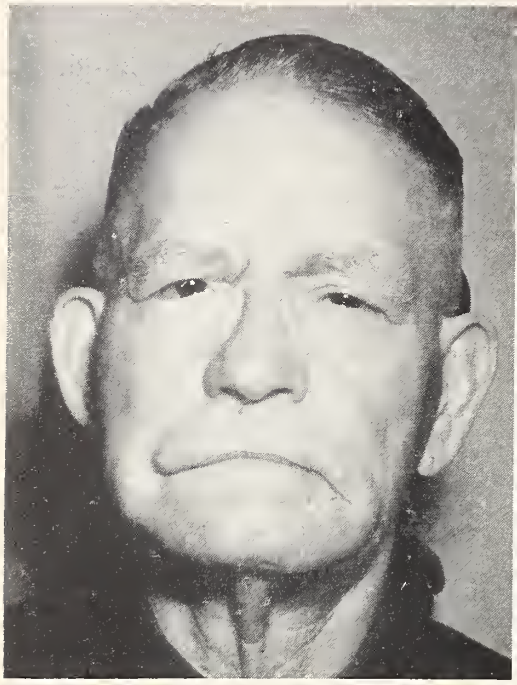

Fig. 14. H. D.—This seventy-one-year-old patient had complete removal of his parotid gland on the right side. Almost the entire gland was involved by the vascular tumor. The facial nerve was sacrificed. The facial paralysis was corrected by utilizing fascia lata from the thigh to correct the facial deformity. It is believed that this is the oldest patient ever successfully operated upon for removal of a hemangioma of the parotid gland.

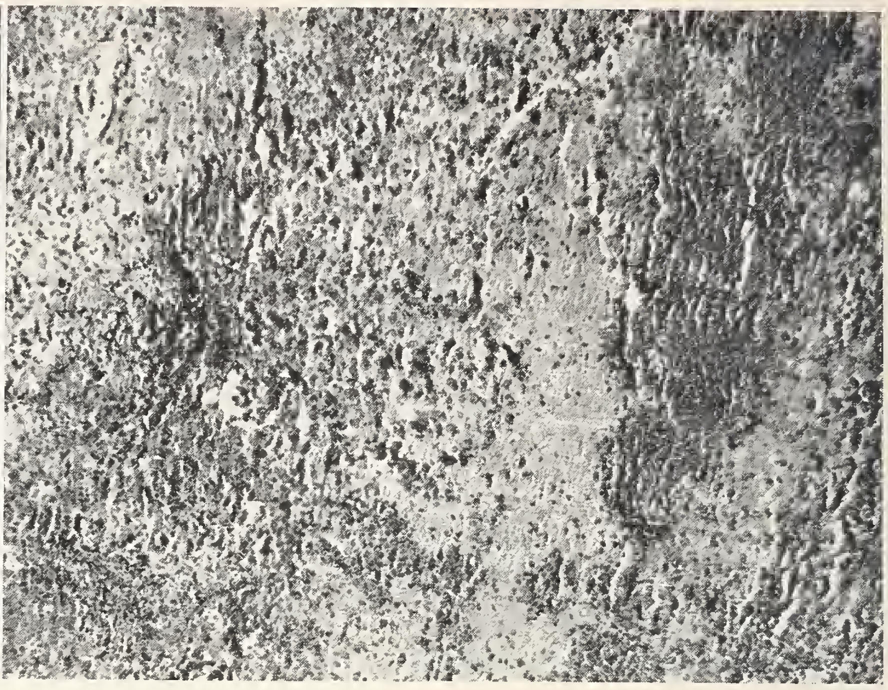

Fig. 15. Microscopic appearance of cavernous hemangioma of parotid gland demonstrating the many blood spaces.

node-bearing area on the affected side. He has been observed for nearly thirteen years without evidence of recurrence.

Case 6. H. D., aged seventy-one, was first seen in February, 1947, complaining of a large swelling on the right side of his face. The swelling had been present since boyhood but had increased markedly in size during the past year. The increase in size of the swelling had been accompanied by severe pain of the lancinating type. He had been unable to sleep for several weeks. He had been seen elsewhere and a diagnosis of a hemangioma had been made and two or three injections of a sclerosing fluid had failed to alleviate his symptoms. The tumor extended from the temporal region, covered the mastoid process, and extended below the angle of the jaw. Pressure caused an increase in the pain and a diminution in the size of the tumor. A bruit could not be heard over the tumor. Because of the vascularity and size of the tumor the patient was advised that removal would probably result in sacrificing the facial nerve with resulting paralysis. This he accepted and with sufficient blood available, surgery was carried out on February 3, 1947. Under intratracheal anesthesia, the external carotid artery was ligated and the entire parotid gland was removed. Bleeding was well controlled by this method and it was not difficult to remove the entire vascular mass down to the masseter muscle. Stensen's duct was ligated. His recovery was uneventful and he left the hospital on the eighth postoperative day. He had a typical facial paralysis, but was entirely free of pain.

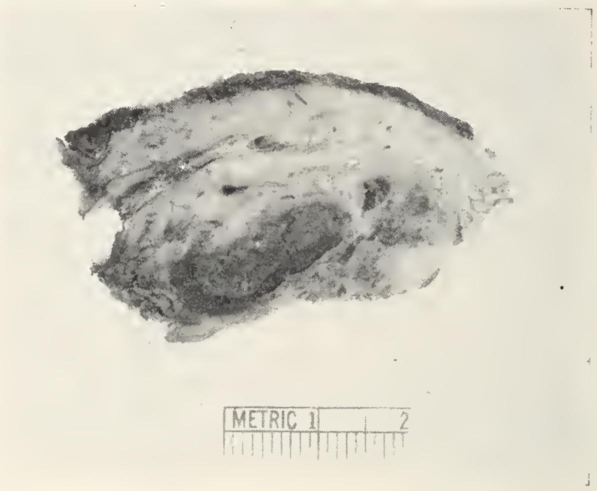

Fig. 16. Cavernous hemangioma of the parotid gland. A small portion of the tumor is shown which shows the extreme vascularity of the tumor.

Pathological diagnosis: Specimen consists of irregular mass of tissue 6 x 5 cm. (Fig. 16). In the center of the mass is an ovoid tumor 3 x 1½ cm. The tumor is hemorrhagic in appearance. The surrounding tissue has the gross appearance of salivary gland.

Microscopically: The tumor nodule is composed of blood spaces most of which are thromboses. The connective tissue contains many foreign body giant cells. These may be the result of sclerosing agent therapy. The whole tumor is surrounded by fairly dense connective tissue capsule. In certain regions the tumor shows cavernous blood spaces. The histological picture is that of a cavernous hemangioma of the parotid gland (Fig. 15).

Diagnosis: Cavernous hemangioma of the parotid gland with partial thrombosis.

On September 15, 1947, strips of fascia lata were inserted under the tarsal plate, upper lip and lower jaw and the loops sutured to the temporal fascia after the method described by J. Barrett Brown. Later a canthoplasty was done and a satisfactory cosmetic result was obtained (Fig. 14).

Hemangiomas of the parotid gland are extremely rare.[8] Those composed of larger vessels are described as capillary hemangiomas.[13] These tumors are benign but often attain considerable size and may invade adjacent structures. They most frequently occur in infants, and often are associated with a superficial vascular nevi. Files of the Registry of Oral Pathology[2] contain only six such tumors in the past twenty years. After a careful search of the literature it is thought that this is the oldest patient ever successfully operated for a hemangioma of the parotid gland.

Summary

1. Parotid gland tumors are rare. The origin of many parotid tumors is not well understood.

2. Mixed tumors of the parotid tend to recur. Even eminent pathologists are inaccurate in being able to predict which ones will recur.

3. Knowledge of the anatomy of the parotid gland will facilitate removal of parotid tumors without injury to the facial nerve.

4. Benign tumors may be treated by simple enucleation. Mixed tumors should be removed by lobectomy and malignant tumors by complete extirpation of the entire gland.

5. Six cases of parotid tumors are presented. One case, a hemangioma of the parotid gland was successfully treated by complete removal of the gland with sacrifice of the facial nerve. Facial paralysis was corrected by the use of fascia lata supporting slings. This case is thought to be the oldest patient successfully treated for a hemangioma of the parotid gland.

RECENT TRENDS IN THE SURGICAL MANAGEMENT OF INFANTILE HYDROCEPHALUS

HENRY W. DODGE, Jr., M.D.
and
MAJOR ROBERT A. MENDELSOHN (MC) USAF
Rochester, Minnesota

INFANTILE hydrocephalus (water on the brain) has intrigued and provoked physicians for many years. Most doctors in their daily practice have had some contact with this condition for it is not uncommon. Murphy found this condition to occur congenitally, with or without spina bifida, in approximately 200 children per 100,000 births. Others have indicated an even higher incidence. The literature on the diagnosis and treatment of hydrocephalus is vast, but, in general, only two main types of hydrocephalus are recognized. These two types are the obstructive and the communicating.

The first of these, obstructive hydrocephalus, in which the ventricles of the brain do not communicate with the cerebrospinal subarachnoid pathways, is most commonly associated with neoplasms of the brain, and its relief is usually obtained by direct attack on the tumor. In those cases in which the disease is not due to neoplasm, congenital atresia of the cerebral aqueduct, congenital bands, hemorrhage, infection and so forth have been described as causative agents. Relief by surgical means will be discussed later in this paper.

Communicating hydrocephalus, in which the cavities of the brain and the pathways of the subarachnoid cerebrospinal fluid are in free continuity, is usually of congenital origin, but may follow inflammation of the meninges. Since the advent of the various chemotherapeutic agents, it has become evident that among children secondary hydrocephalus due to obliteration of the basilar cisterns may be one of the unexpected complications which develops after successful treatment of an acute phase of meningitis with antibiotics.

Classically the treatment of hydrocephalus in children has fallen into two categories. First, attempts have been made to reduce the total quantity of cerebrospinal fluid produced by coagulation or avulsion of the choroid plexuses of the cerebral ventricles,[1,8,11] dehydration, repeated spinal or ventricular punctures, ligation of the carotid arteries[3] in the neck, sympathectomy and so forth.[10]

The second general method for the relief of infantile hydrocephalus has been the attempt to divert the cerebrospinal fluid from its customary subarachnoid pathways to other depots. In this regard it is of interest to realize that it is relatively difficult to devise a "new" operation for the treatment of hydrocephalus, for over the years practically every body cavity or space, potential or real, has been utilized in the attempt to arrest the inexorable progression of this condition.

Spontaneous remission of severe hydrocephalus does occur and cases have been reported. In cases of severely progressive disease, however, it is hazardous to wait or hope for spontaneous remission since the disease can rapidly develop to a point where surgical intervention will not help.

The clinical appearance of the hydrocephalic child need not be described here for it is familiar to all physicians. In the first few weeks of life hydrocephalus in the early stages of development may not be easily detectable. More than one discerning doctor has found the successive routine measurements of the head on postnatal visits to be revealing.

The attempt to reduce the production of cerebrospinal fluid has, except in a few hands, been unrewarding. Diversionary operations have been common for, to all intents and purposes, the problem of the surgical treatment of infantile hydrocephalus seems a simple one. Yet over the

The opinions expressed in this publication are not necessarily those of the Department of the Air Force or Department of Defense.

Dr. Dodge is from the Section of Neurologic Surgery.

years, except for sporadic successes, most therapeutic attempts have yielded discouraging results.

The most commonly employed procedures for the relief of hydrocephalus resulting from an obstruction of the ventricular pathways (obstructive hydrocephalus), except direct attack on a neoplasm, have been third ventriculostomy, that is, the establishment of a communication between the third ventricle of the brain and the basal subarachnoid cisterns,[12] and detour operations. In the detour operations the cerebrospinal fluid has been routed from the lateral ventricles in the brain to the cisterna magna in the posterior cranial fossa[14] (Fig. 1), to the mastoid antrum[7] (Fig. 2), to the pleural[4] or peritoneal cavities[9] (Fig. 3), or to the ureter after removal of the ipsilateral kidney.

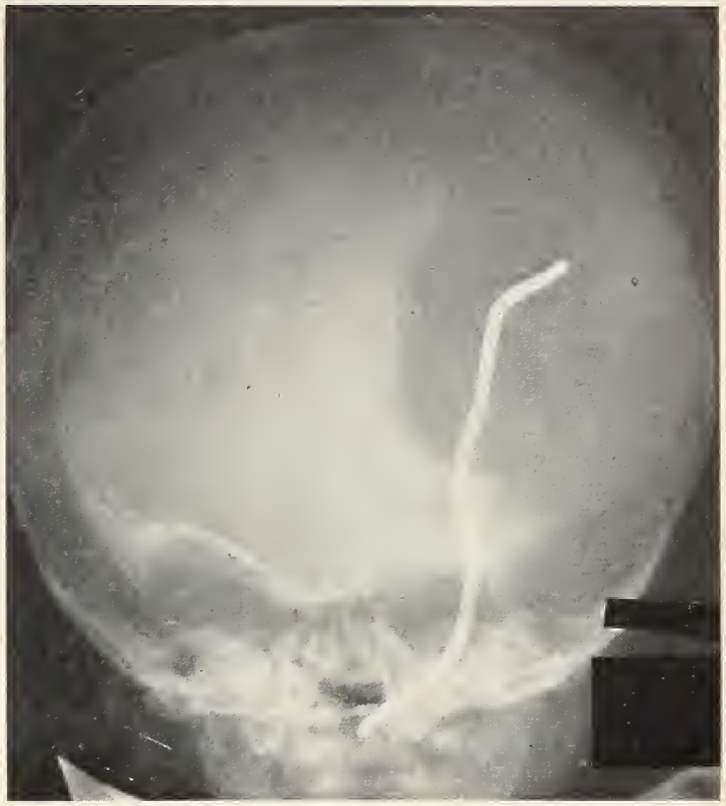

Fig. 1. Ventriculocisternal shunt.

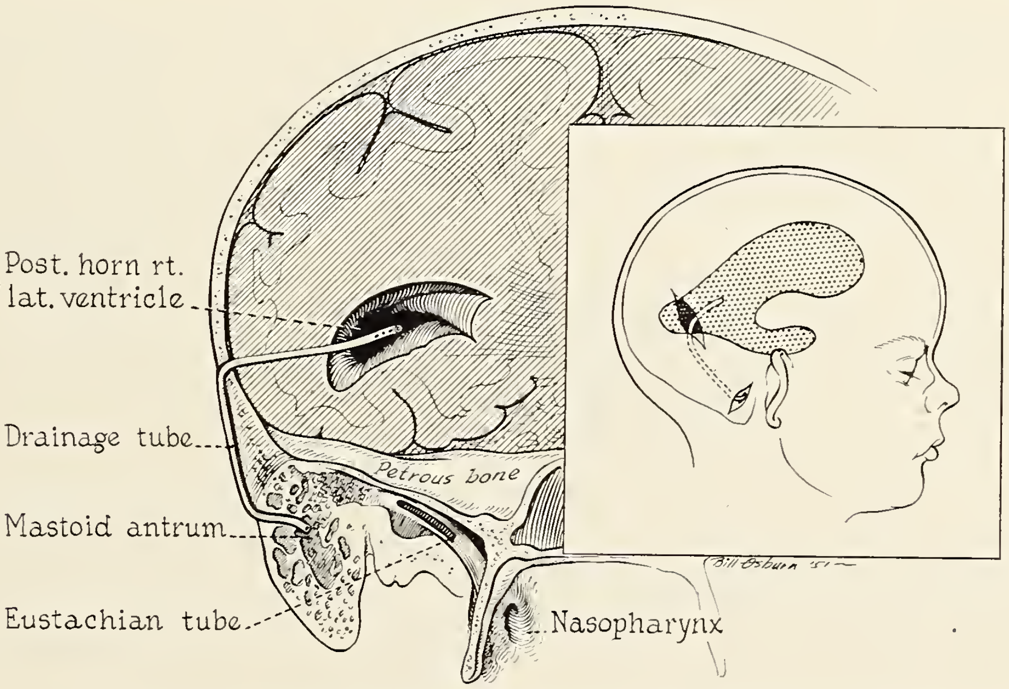

Fig. 2. Ventriculomastoid shunt, modified from Nosik. (From Svien, H. J., Dodge, H. W., Jr., and Lake, C. F.: Ventriculomastoid Shunt in the Management of Obstruction to the Aqueduct of Sylvius in the Adult: Report of Case. Proc. Staff Meet., Mayo Clin., 27:215-218 [May 21] 1952.)

For communicating types of hydrocephalus in which diagnostic ventriculography, dye tests and encephalography demonstrated free communication between the ventricular system and the cerebrospinal subarachnoid pathways, the same ventricular short circuits to extra-nervous depots have been employed, or other methods of diversion were devised from the spinal subarachnoid space to the subcutaneous tissues of the back (Seton)[13] (Fig. 4), vertebral body,[16] retrohepatic space, omental bursa (Fig. 5*a*), peritoneal cavity,[2,5,15] and ureters (Fig. 5*b*). This is done because although the ventricles and subarachnoid spaces are in free communication, the cerebrospinal fluid does not seem to be adequately absorbed or to gain egress from the nervous system.

Although the large majority of these procedures has been tried in the past with only meager reward, recently a combination of factors has resulted in renewed interest in the treatment for hydrocephalus and an awakening of effort has occurred.

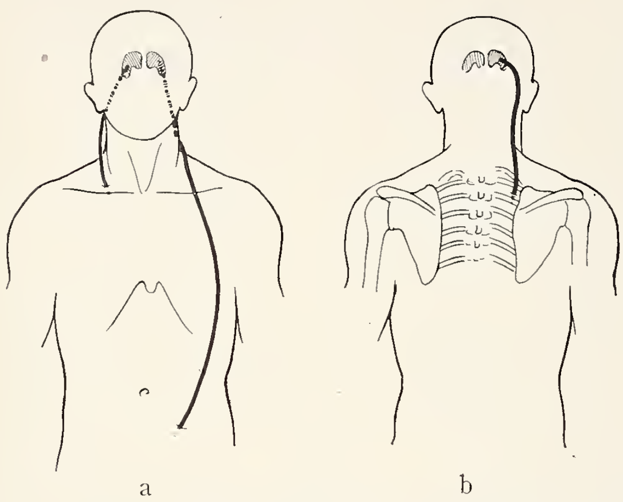

Fig. 3. (*a*) Ventriculopleural shunt (through the supraclavicular space), and ventriculoperitoneal shunt; (*b*) ventriculopleural shunt (through the second intercostal space posteriorly).

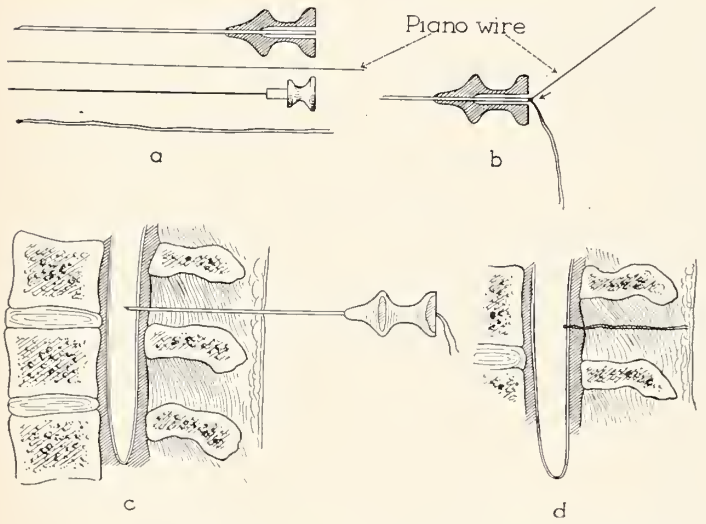

Fig. 4. Seton procedure: (a) Seton needle with stylet and knotted silk string; (b) method of inserting silk; (c) needle and knotted silk in place in the subarachnoid space; (d) knotted silk in place in the subarachnoid space and subcutaneous tissues after withdrawal of needle.

Since the last great war improved surgical techniques, new materials (such as plastics), a wider therapeutic spectrum for antibiotics, more adequate anesthesia for children, regulation of blood and electrolytes, and more enlightened nursing and supportive care have encouraged renewed surgical effort.

The increasingly wide cognizance that progressive enlargement of the head in the first year of life can be due to brain tumor or subdural hematoma, has tended to remove many patients having these conditions from the large indeterminate group of patients having progressive hydrocephalus. Many infants having subdural hematomas, and some infants having certain types of brain tumors or congenital cysts may be spectacularly salvaged by early recognition and surgical treatment.

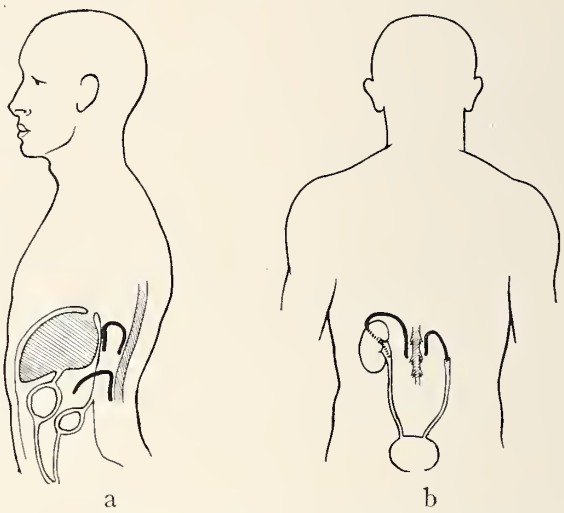

Fig. 5. (*a*) Subarachnoid retrohepatic shunt *(above)* and shunt from subarachnoid space to the lesser omental bursa (*below*). (*b*) Subarachnoid reno-ureteral shunt (experimental) *(left)* and subarachnoid ureteral shunt *(right)*.

An occasional case such as the one reported herein may serve to spur surgeon and clinician alike to greater diagnostic accuracy when confronted with progressive enlargement of the head of unknown etiology. This case is only one example of why these children need to be carefully studied as to the cause of their rapidly enlarging heads.

Report of Case

A baby boy, two months of age, was admitted to the Mayo Clinic because of rapid enlargement of the head since birth. His mother had not suffered any illness during pregnancy. The infant was delivered without instruments after two hours of labor. At birth the circumference of the head was 35 cm. On routine checkup at one month the circumference of the head was 40.5 cm., and at two months it was 45.5 cm. Development had been normal in all other respects up to the time of the child's admission.

Examination showed that the fontanel was bulging and that the cranial sutures were separated. Roentgenograms of the skull confirmed these findings. Bilateral puncture of the fontanel did not reveal subdural hematoma. Results of dye studies were indeterminate. Ventriculography revealed marked thinning of brain substance, but air could not be seen in the third or fourth ventricle. The infant was taken home and returned in one month, during which time the head had enlarged 4 cm.

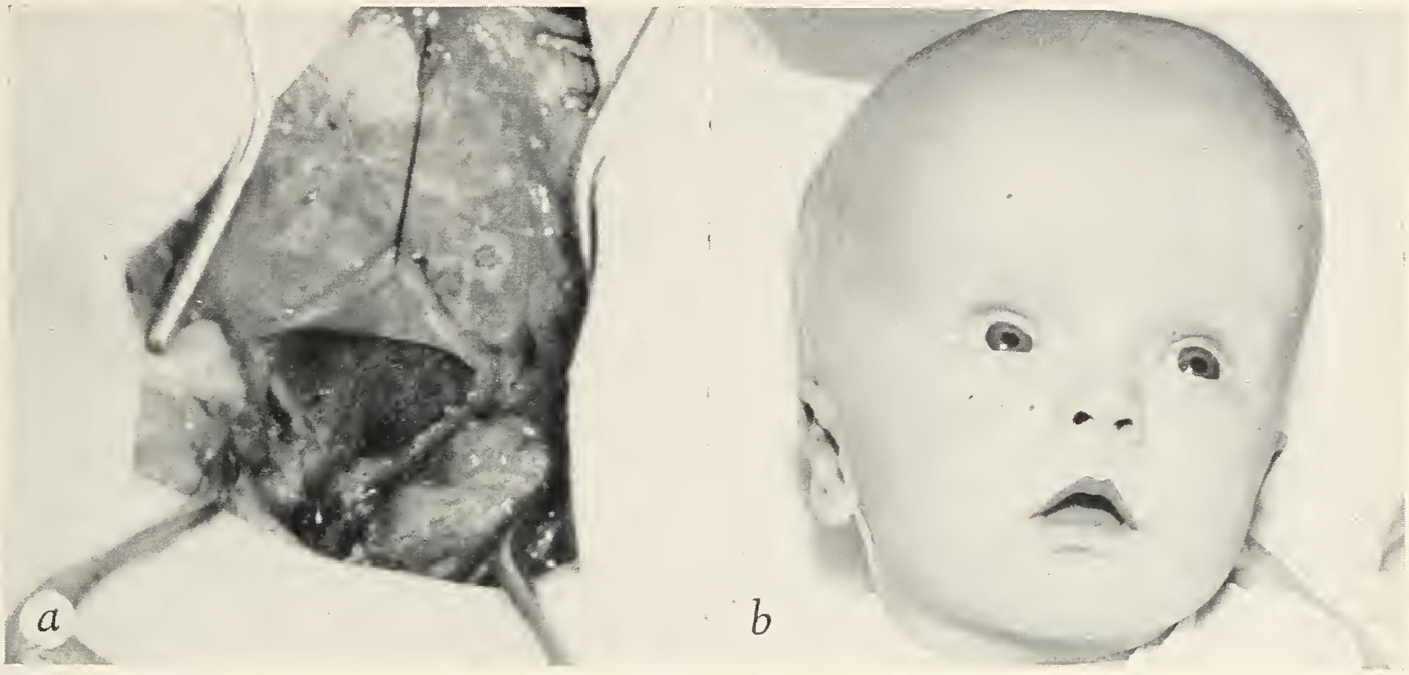

Fig. 6. *(a)* Suboccipital craniectomy showing a congenial cyst blocking the fourth ventricle. *(b)* View of patient after operation.

Suboccipital craniectomy was performed at this time and a cyst was encountered over the fourth ventricle (Fig. 6*a*). This proved to be the dilated roof of the fourth ventricle, the foramina of Luschka and Magendie being absent. The fourth ventricle was then unroofed, allowing free communication between the ventricular and subarachnoid spaces. During the postoperative hospital stay, the fontanel remained soft (Fig. 6*b*).

The last report from the infant's home physician, nine months after operation, indicated that the patient's head had grown at a normal rate for his size and age, and that his general health was good.

Realization that a number of hydrocephalic infants have other anomalies of the nervous system which most probably will not be cured or even ameliorated by relief of intracranial pressure, has tended to lessen the harsh judgment of operative procedures designed to relieve hydrocephalus. When the final analysis of results is considered and made, surgeons should be more willing to modify the "all or none" dictum and should be satisfied with relief of progressive pressure, regardless of whether the success is great or small.

Moreover, the feeling has become more prevalent regarding these pressure-relieving operations, that they are not considered as "cures" *per se,* but that they allow relief from progressive pressure until some sort of spontaneous cerebral compensation can occur. Such a philosophy promotes rather than discourages attempts at therapy.

Unfortunately it is not difficult to predict the clinical result in the case of an unattended infant having severely progressive hydrocephalus; most usually it is disastrous. However, after relief from pressure has been obtained, despite the severity of pre-existing damage, it is often exceedingly difficult to foresee the eventual result. One may be very agreeably surprised when a child with moderate damage to the brain is spared the inexorable march of hydrocephalus and proves in later life to be a relatively useful member of the community.

So, while there are seemingly few "new" operations for the relief of the patient having hydrocephalus, recent trends relative to technique, materiel, diagnosis and thinking on the subject should result in concentrated diagnostic and therapeutic effort, if possible, for each infant afflicted with progressive enlargement of the head rather than abandonment of the patient to the pitiful group of incurable progressive hydrocephalics.

CONDITIONS MISTAKEN FOR LEUKEMIA IN CHILDREN

STEPHEN D. MILLS, M.D.
Rochester, Minnesota

THE familiarity of the lay public with medical terms is nowhere better illustrated than in the case of leukemia, as this is a malignant disease which is particularly prevalent in childhood as well as in the later decades of life (Fig. 1). Many of its victims have received much newspaper publicity which always arouses concern and sympathy among the reading public. Since leukemia is universally fatal, it is important to be certain of the diagnosis before causing parents to suffer the severe anxiety that accompanies the pronouncement of such a disease in their child. A further reason for accurate diagnosis is that the treatment of leukemia, unsatisfactory as it is in saving life, is most effective in alleviating symptoms when begun early in the course of the illness.

There is increasing evidence that the incidence of leukemia is on the upgrade in all age groups. This seems to be true even when allowance is made for the increase that is attributable to better methods of detection and to awareness of the possibility of the disease on the part of both physicians and the public.

It should be pointed out in this connection that with the continued and drastic reduction in childhood mortality from infections there has been a radical change in the relative importance of deaths from cancer as a whole among children. Data published in 1949 for children insured in one large life insurance company[2] show that cancer, including leukemia and Hodgkin's disease, is now second only to accidents as the ranking cause of death in the age group one to fourteen years inclusive and leads all other diseases in the age group five to nine years. These data also indicate that leukemia is the most common type of fatal cancer in children—that it accounts for nearly half of the deaths from cancer in the age group one to four years inclusive, for a little more than two-fifths in the age group five to nine and for more than a third in the age group ten to fourteen. In addition, these data disclose that there has been a significant increase in deaths from leukemia at all ages from one to fourteen years inclusive but especially in the age group five to nine years when the period 1943 to 1947 inclusive is compared with the period 1930 to 1934 inclusive.

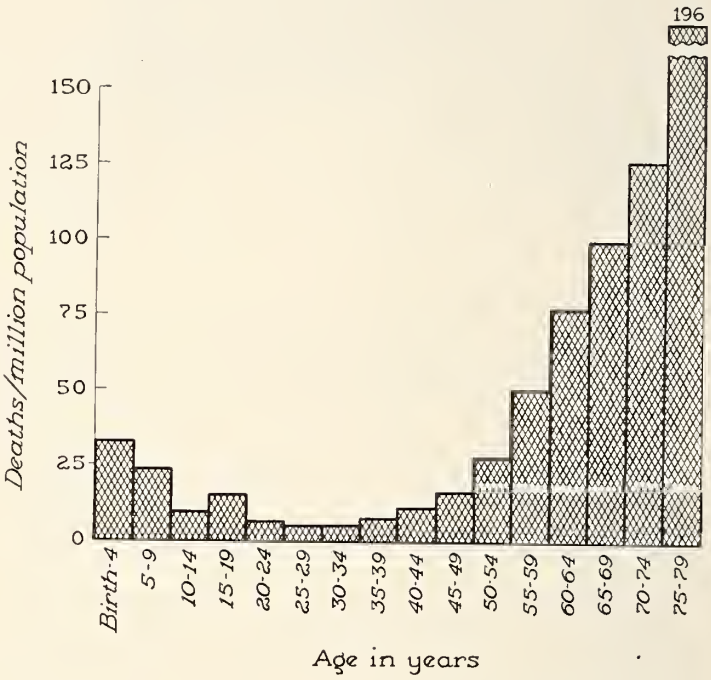

Fig. 1. Age incidence at death from lymphatic leukemia in the white male population of the United States for the year 1949. (Reproduced with permission from: Gilliam, A. G.: Age, sex, and race selection at death from leukemia and the lymphomas. Blood., 8:693-702 (Aug.) 1953.

Sachs and Seeman[3] in a statistical study showed that in the period from 1931 to 1940 there was an over-all increase of 60.9 per cent in mortality from leukemia. In the age group under one year the increase was 75.7 per cent; in the age group one to four years, 55.2 per cent; and in the age group five to fourteen years, 46.1 per cent.

Gilliam,[1] in the most recently available study, has shown that the incidence of lymphatic leukemia in children less than five years of age is greater than at any age up to fifty-five years.

Acute leukemia should be suspected in a child who has been ill for some time with fever, anemia

and enlargement of the liver, spleen and lymph nodes and who may have purpura or bleeding manifestations and leukocytosis with an increase in lymphocytes, many of which may be immature in development. In such cases, however, only careful examination of all the formed elements of the blood as to their quantity and quality may eventually afford the answer, and at times it will be necessary to examine the site of formation of the blood, namely the bone marrow, to arrive at a diagnosis that is not apparent from a study of the peripheral blood. Furthermore, one must remember that the blood of small children reacts with greater lability than that of adults and that the normal values for the various formed elements of the blood differ from those of older patients (Figs. 2, 3 and 4). The variability in the number and type of leukocytes in young children must be taken into account when a child is suspected of having leukemia.

Because of the importance of an accurate diagnosis when the question of leukemia in a child has been raised, it seemed worth while to determine which conditions are most likely to be mistaken for leukemia. For information on this point, I have viewed the records of forty-four children who were seen at the Mayo Clinic in the years 1949 to 1952 inclusive and who were suspected of having this disease but who, in every instance, were proved to have some other condition that was responsible for the findings suggestive of leukemia. All but four of this group of children were less than five years of age and most were two years of age or less.

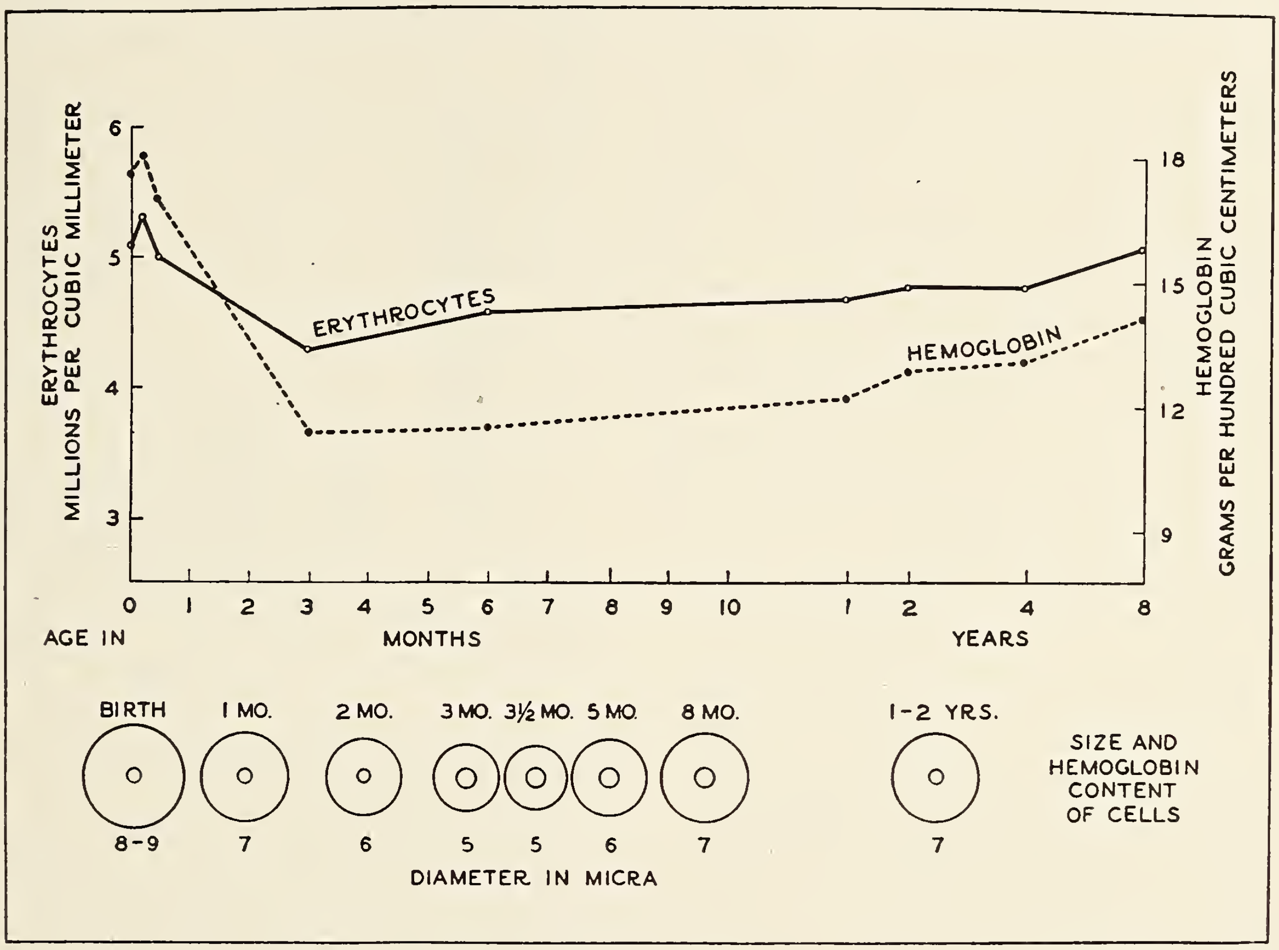

Fig. 2. Normal values for erythrocytes and hemoglobin at various ages in childhood. (Reproduced with permission from: Blackfan, K. D. and Diamond, L. K.: Atlas of the Blood in Chidren. Page 9. New York: The Commonwealth Fund, 1944.)

By grouping the conditions which were present in the forty-four patients suspected of having acute leukemia, it was found that the great majority had an acute infection to which their blood reacted with an unusual increase in total leukocytes or lymphocytes or both (Fig. 5). This is the so-called leukemoid reaction which is familiar to the hematologist and the internist and which occurs in response to certain infections, intoxications, malignant disease with metastasis to bone, and severe hemorrhage. It is well known that pertussis may cause a high leukocyte count with a predominance of lymphocytes, and this infection was found to be the basis of the disturbance in four children, all less than a year of age, one child having 130,000 leukocytes per cubic millimeter of blood of which 80 per cent were lymphocytes of immature types. Others in this group had infections of the respiratory, intestinal and urinary tracts or evidence of sepsis. Five children were proved to be suffering from infectious mononucleosis which is assumed to be of viral origin and may easily be confused with leukemia because of the enlarged liver, spleen and lymph nodes and because of the lymphocytic increase in the blood. Careful study of the peripheral blood smear for atypical lymphocytes of Downey and the presence of a high heterophil titer established the true diagnosis in these cases.

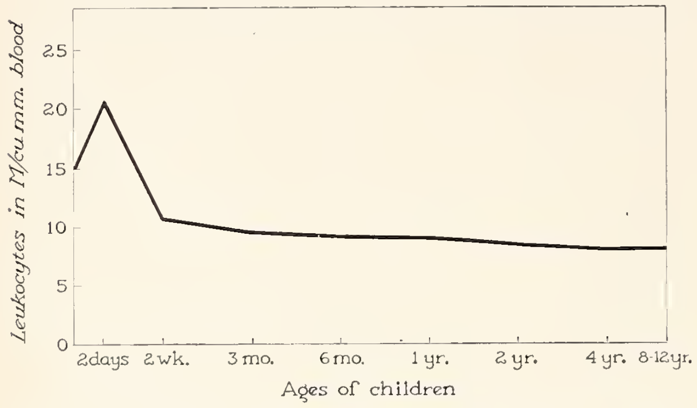

Fig. 3. Normal values for total leukocytes at various ages in childhood. (Reproduced with permission from: Blackfan, K. D. and Diamond, L. K.: Atlas of the Blood in Children, page 8, New York, The Commonwealth Fund, 1944.)

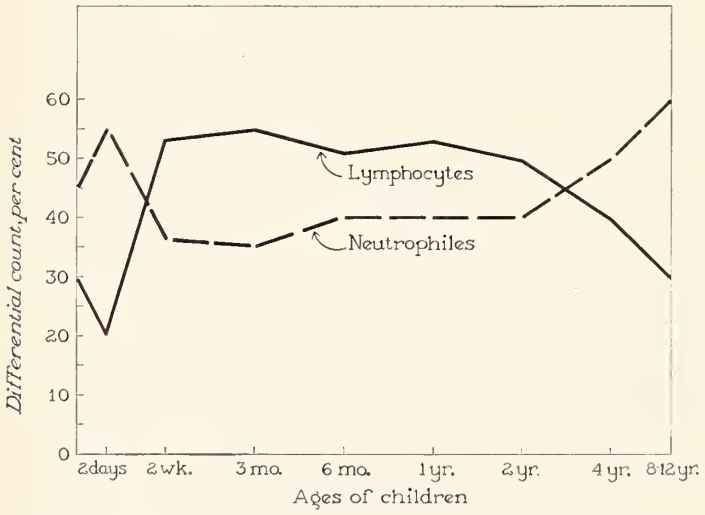

Fig. 4. Normal differential counts for neutrophils and lymphocytes at various ages in childhood. (Reproduced with permission from: Blackfan, K. D. and Diamond, L. K.: Atlas of the Blood in Children, page 8, New York, The Commonwealth Fund, 1944.)

Two children had an interesting condition, described by Smith[4] and called by him "acute benign lymphocytosis," which was characterized by elevated leukocyte and lymphocyte counts without immaturity of the latter type of cell. Both of these patients recovered.

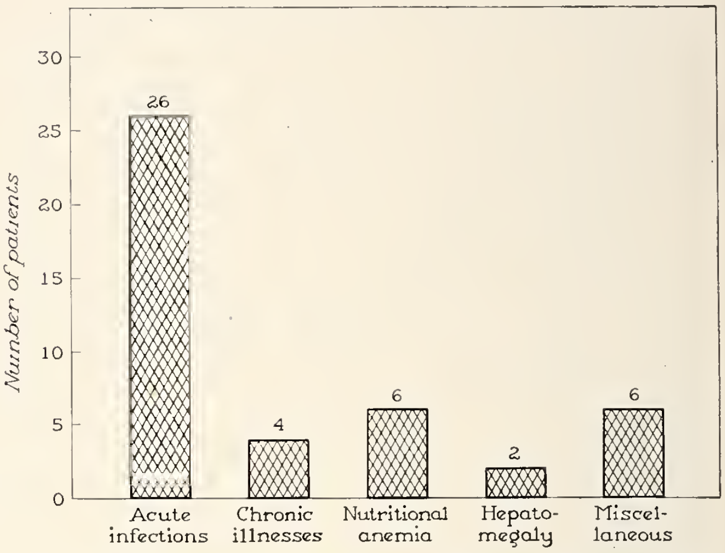

Fig. 5. Conditions which simulated leukemia in 44 children seen at the Mayo Clinic in the period 1949 through 1952.

Four children had chronic illnesses which caused reactions in their blood suggestive of leukemia. One of these children had rheumatoid arthritis, one had infantile cortical hyperostosis and the other two had chronic disorders of the skin, namely, eczema and urticaria pigmentosa respectively, which were secondarily infected.

Six children less than eighteen months of age had anemia classified as nutritional since their diets lacked the ingredients deemed essential in building blood successfully; all responded to improvements in their diets. All habitually drank milk to the exclusion of meat, eggs, cereals, vegetables and fruits. Two children with enlarged livers were found to have a hepatoma and a granuloma of the liver, respectively, but they did not have leukemia.

In the group of children with miscellaneous conditions were a sixteen-month-old child with acquired hemolytic anemia, a two-year-old child with bleeding from the bowel, a two and one-half-year-old girl with a granulocytopenia and relative lymphocytosis resulting from the toxic reaction to an antibiotic drug, a five-year-old boy whose mother feared leukemia because he bled from the site of a penicillin injection, and an eleven-year-old girl with a brain tumor. None of these proved to have leukemia.

In addition to the diseases encountered in this series of forty-four cases, there are other conditions which may be mistaken for leukemia in children. These include (1) the collagen diseases such as rheumatic fever, and infections such as typhoid fever, osteomyelitis, congenital syphilis, viral hepatitis and other viral diseases, and fungous infections; (2) malignant neoplasms, such as neuroblastoma, with metastasis to bone; and (3) intoxications such as poisoning from heavy metals.

It is not always possible to make a definite diagnosis in all children who are suspected of having leukemia. This is illustrated in the case of an eighteen-month-old boy who was referred for examination because leukemia was suspected but who was not in this series of forty-four patients. Repeated examinations of this child's blood and bone marrow failed to disclose the true nature of his disorder, yet he died of leukemia three years later. It must be emphasized that only continued observation and repeated examination of the blood will disclose the nature of the disease in most instances.

Conclusions

When confronted with a very young child suspected of having leukemia because of anemia, enlargement of the liver, spleen and lymph nodes, purpuric manifestations, and abnormal increase of the leukocyte and lymphocyte counts with or without immaturity of the latter cells, one must be exceedingly cautious in making a diagnosis of leukemia because of the extreme lability of the blood of young children in response to certain acute or chronic illnesses, intoxications, malignant diseases, and severe hemorrhage. Careful and continued study of the peripheral blood and bone marrow should enable one to exclude the diagnosis of leukemia when the child actually has some other disease.

DEATHS FROM PEPTIC ULCER IN MINNESOTA DURING 1952

JAMES H. CASEY, M.D.
Minneapolis, Minnesota

DURING the month of September, 1952, a seventy-two-year-old farmer went ninety miles up the North Shore of Lake Superior for a "fast." During the next nine days he ate nothing and drank only water and alcohol. On September 20, he was brought in to a hospital suffering from a perforated duodenal ulcer which had manifested itself twenty-four hours previously. He was moribund on admission to the hospital and died before an adequate examination could be performed.

Perhaps at the other extreme is the story of a seventy-seven-year-old man with cancer of the lung. While he was in the hospital for diagnosis during August, 1952, it was decided that the tumor was inoperable, but before he could be discharged, a serious hemorrhage from a gastric ulcer occurred. He was subjected to an emergency gastric resection during which a large hepatic metastasis was found. He died on the tenth postoperative day from general debility arising from the operation and pulmonary carcinoma.

Between these extremes lie the remaining ulcer deaths in Minnesota for the year 1952. Most of them are far less exciting in their circumstances but it was with a view toward analyzing all of these deaths in order to gain any useful information that they may supply that this study was done.

Source of Information Concerning the Ulcer Deaths

A list of patients probably dying of peptic ulcer in 1952 was obtained from the State of Minnesota Department of Vital Statistics.[2] This basic source of information was supplemented by questionnaires sent out to the attending physicians. One half of the patients were from the Twin City area and the other half were from the remainder of the state. In addition, the records of Minneapolis General Hospital and Ancker Hospital were combed for information which some attending physicians in the Twin City area could not furnish. This was done because of the possibility that many of these patients may have been seen at some time in these institutions on an emergency basis during a bleeding episode. Many local physicians were also reached for information by telephone.

TABLE I. CLASSIFICATION OF DEATHS ACCORDING TO TYPE OF COMPLICATION

Hemorrhage	59	(46%)
Perforation	36	(28%)
Perforation with hemorrhage	7	(5.5%)
Obstruction	17	(13%)
After elective surgery	10	(8%)
Total	129	(100%)

From the Department of Vital Statistics an original list of 143 patients who may have died as a result of peptic ulceration was drawn up. On further investigation eleven of these were found to have died of other causes and three patients were in the doubtful category. Consequently in the final analysis, 129 people died from complications of peptic ulcer in this state in 1952. Two of these had advanced carcinoma, one of the lung and the other of the larynx. If allowance is made for these two, then only 127 patients would have survived the year had they not had ulcers.

We have supplemented the information obtained from the Department of Vital Statistics in 119 of these 129 patients. The remaining ten are lost to followup. Seventy of these 129 patients had other significant although not necessarily fatal diseases excluding the two with cancer. These were for the most part arteriosclerosis in one form or another, diabetes, or emphysema. While a few had serious heart disease and were in failure at the time of their complication, they are listed as ulcer deaths.

Causes of Death

Table I shows a breakdown of the deaths into various categories. It is not surprising to see that hemorrhage heads the list. The prominence of

TABLE II. CLASSIFICATION OF DEATHS ACCORDING TO AGE, SEX, AND LOCATION

Age	Average age 65 years (youngest 32 years, oldest 89 years)
Sex	102 males and 27 females
Location	78 duodenal 32 gastric 3 combined 16 unknown
	129 total

TABLE III. CIRCUMSTANCES SURROUNDING DEATH IN 95 OUT OF THE 102 CASES OF HEMORRHAGE AND PERFORATION

Complication	Well Attended by a Physician During Final Episode	Moribund When First Seen	Dead When Seen	Percent Died Without Care
Hemorrhage	48	3	4	13%
Perforation	32	2	0	5.7%
Perforation with Hemorrhage	6	0	0	0%
	86	5	4	9.5%

peptic ulcer as an important cause of death is due mainly to this complication.[4] However, that perforation should follow so closely with 28 per cent of the total, appears unusual in that it is generally felt that the mortality rate for perforation has decreased markedly since the advent of antibiotics. Our mortality rate in this clinic for perforation is 6.4 per cent in cases handled since 1942, with no deaths during the last five years. Perhaps this very reliance on the antimicrobial agents accounts in part for the many deaths from perforation in that today there is a greater tendency to handle this catastrophe without surgery. The non-operative treatment of perforated ulcers utilizing constant gastric suction was abandoned in this clinic in 1935[5] except for early small perforations without pneumoperitoneum or the "forme fruste" type in which a perforation closes over shortly after the onset of pain. The patient with this latter type is often clinically well when first seen but has a small pneumoperitoneum demonstrable on x-ray. The non-operative treatment of large perforations with much free air in the peritoneal cavity and great peritoneal contamination from food carries a very high mortality rate. With safer gastric resection now common, one would also expect to see the deaths from obstruction decline.

TABLE IV. PEPTIC ULCER FATALITIES OCCURRING AFTER STRESS SITUATIONS IN THE 102 CASES OF FATAL HEMORRHAGE, PERFORATION, OR BOTH

	Hemorrhage	Perforation	Perforation with Hemorrhage
Asthma, spontaneous pneumothorax, or Cor pulmonale in failure	3	2	0
Congestive heart failure	1	3	1
Poliomyelitis	1	0	0
Recent fracture	1	1	0
Meningitis	1	0	0
Cerebral Vasc. Accident	1	0	0
Peritonitis	1	0	0
Total Incidence	9 (16%)	6 (17%)	1 (14.3%)

Age, Sex, and Location of the Ulcers

Table II bears out the well known facts that peptic ulcer deaths are more common in elderly individuals and that it is a more frequent disease in males. All types of complications follow this general pattern concerning age, sex, and location except that the average age in the obstructed group was sixty-eight years and that all ulcers in this class were duodenal. The average age of those dying after elective surgery was fifty-four years.

Conditions Surrounding the Management at the Time of Death

One frequently hears of people experiencing fatal upper intestinal hemorrhages or perforations in remote areas far from medical attention. What risk is involved for such catastrophes in people with peptic ulcer symptoms? Out of 102 cases of death due to hemorrhage, perforation, or a combination of the two, information concerning the exact nature of demise was obtained in ninety-five instances. (Table III) Five patients were moribund on admission to a hospital or when they were first placed in a physician's care, and four died before medical aid reached them, a percentage of 9.5 per cent. Typical histories here include patients who never consulted a physician at any time, bleeding while driving an automobile, and the tragic case of the patient who bled to death while receiving a transfusion in an ambulance on the way to a hospital for emergency surgery. At least six of these nine casualties had a history of epigastric distress for some years before the final incident and two had had previous hemorrhages.

TABLE V. PREVIOUS COMPLICATIONS 111 OUT OF 129 CASES

Hemorrhage	23
Perforation	10
Esophagitis with obstruction	1

Stress and Peptic Ulcer

That stress situations may activate a dormant peptic ulcer or instigate conditions leading to acute ulceration is well known. Sixteen fatal hemorrhages or perforations occurred after the development of stress situations. (Table IV). Asthma and allied respiratory crises appear to be particularly serious offenders. Cortisone may have been instrumental in two of these, and in two of the nonrespiratory induced situations, renal insufficiency and the bleeding tendency which often accompanies it may have played some part. Four of the sixteen had a definite ulcer history, seven had no past history, and this factor is unknown in the other five.

Past History of Peptic Ulcer

As one can see in Table V, over ⅔ of the 111 cases in which full information is available, died as a result of their first complication. Of the thirty-four patients with a history of hemorrhage or perforation, the majority had only one episode of one or the other in the past. None of the ulcer victims had a modern gastrectomy before the final episode; however, eight out of 120 patients did have some previous gastric surgery as follows: six had earlier perforations closed, one had a gastrojejunostomy, and one had a 50 per cent gastric resection. No one in the entire series had a vagotomy.

The majority of patients had some warning that a fatal accident might happen in that ninety-two of the 114 cases in which full information is at hand had a history of ulcer distress. There does not seem to be any correlation between the duration of ulcer symptoms and the severity of the ulcer diathesis. Many patients had histories of ten to twenty years' duration without any significant difficulties only to have a fatal complication occur in 1952, while at least twenty-two patients had no previous symptoms.

The next part of this paper will deal with each group of complications individually, as follows: (1) deaths due to hemorrhage, (2) perforation, (3) perforation with hemorrhage, (4) obstruction, and (5) deaths after elective surgery for peptic ulcer.

Hemorrhage

In the fifty-nine cases of hemorrhage supplemental information was obtained in fifty-six instances. The average age at the time of death, sex, and location of the ulcer are typical of the entire series of 129 patients. (Table II).

As regards a history of peptic ulcer, nine out of fifty-two patients had no previous history before their final episode and thirteen had a history of less than one year. Eighteen out of fifty patients had the previous complication of hemorrhage, usually only one episode, and two had previous perforations. It is interesting to note that fourteen of these twenty who had serious difficulty with the ulcer diathesis in the past were in good health otherwise and consequently could be considered candidates for earlier elective operations which may have been lifesaving.
